Abstract. We reconstruct the power spectrum of primordial curvature perturbations by applying a well-validated non-parametric technique employing Tikhonov regularisation to the first data release from the Planck satellite. To improve the reconstruction on small spatial scales we include data from the ground-based ACT and SPT experiments, the WiggleZ galaxy redshift survey, the CFHTLenS tomographic weak lensing survey, and spectral analysis of the Lyman-\(\alpha\) forest. The reconstructed scalar spectrum (assuming the standard ΛCDM cosmology) is not scale-free but has an infrared cutoff at \(k \lesssim 5 \times 10^{-4} \text{ Mpc}^{-1}\) and several \((2\ldots3)\sigma\) features, of which two at wavenumber \(k/\text{Mpc}^{-1} \sim 0.0018\) and 0.057 had been seen already in WMAP data. A higher significance feature at \(k \sim 0.12\text{ Mpc}^{-1}\) is indicated by Planck data, but may be sensitive to the systematic uncertainty around multipole \(\ell \sim 1800\) in the 217\times217 GHz cross-spectrum. In any case accounting for the ‘look elsewhere’ effect decreases its global significance to \(\sim 2\sigma\).

Keywords: primordial gravitational waves (theory), cosmological parameters from LSS, cosmological parameters from CMBR, cosmological perturbation theory

ArXiv ePrint: 1510.03338
1 Introduction

Detailed knowledge of the primordial curvature perturbation is essential in order to elucidate the physical mechanism which generated it. This is widely believed to be an early quasi-de Sitter phase of exponentially fast expansion (inflation), usually assumed to be driven by a scalar field whose ‘slow-roll’ to the minimum of its potential generates a close to power-law spectrum of curvature perturbations (with small logarithmic corrections called ‘running’).

A power-law spectrum is usually assumed when extracting cosmological parameters from observations of the cosmic microwave background (CMB) and large-scale structure (LSS) in the universe. The actual primordial power spectrum (PPS) cannot in fact be directly extracted from the data. This is because relevant cosmological observables are given by a convolution of the primordial perturbations with a smoothing kernel which depends on both the assumed world model and the assumed matter content of the universe. Moreover the deconvolution problem is ill-conditioned so a regularisation scheme must be employed to control error propagation [1].

We have demonstrated in some detail [2] that ‘Tikhonov regularisation’ can reconstruct the primordial spectrum from multiple cosmological data sets and provide reliable estimates of both its uncertainty and resolution. Using Monte Carlo simulations we investigated several methods for selecting the regularisation parameter and found that generalised cross-validation
and Mallow’s $C_p$ method give optimal results. We applied our inversion procedure to data from the Wilkinson Microwave Anisotropy Probe (WMAP), other ground-based small angular scale CMB experiments, and the Sloan Digital Sky Survey (SDSS). The reconstructed spectrum (assuming the standard ΛCDM cosmology) was found to have an infrared cutoff at $k \lesssim 5 \times 10^{-4}$ Mpc$^{-1}$ (due to the anomalously low CMB quadrupole) and several features with $\sim 2\sigma$ significance at $k$/Mpc$^{-1} \sim 0.0013$–0.0023, 0.036–0.040 and 0.051–0.056, reflecting the ‘WMAP glitches’ [2]. We noted that more accurate data, such as from the Planck satellite, would be required to test whether these features are indeed real.

In this paper we apply our method to the first data release from the Planck satellite [3], and ground-based experiments such as Atacama Cosmology Telescope (ACT) [4] and South Pole Telescope (SPT) [5], as well as the WiggleZ galaxy redshift survey [6], analysis of the Canada-France Hawaii Telescope Lensing Survey (CFHTLenS) [7], and spectral analysis of the Lyman-α forest [8]. Note that the Planck collaboration has estimated cosmological parameters from their data by assuming a power-law PPS, with possible running included [9].

Several authors have adopted a more general parameterisation of the PPS and used Monte Carlo Markov Chain (MCMC) analysis to simultaneously estimate the PPS and the background cosmological parameters. However the relative crudity of the modelling means that the resolution of the estimated PPS is limited. Up to 4 tilted wavenumber bins with variable locations were used in [10], while [11] employed up to 5 movable ‘knots’ with linear and cubic spline interpolation and assessed the Bayesian evidence for each additional knot. The Planck team applied a similar procedure to their second data release for up to 8 movable knots with linear interpolation [12]. A cubic spline PPS with 20 fixed knots was applied in analysis of the Planck, ACT, SPT and BOSS CMASS data in [13], and the same method was implemented with 12 fixed knots for the second Planck data release [12]. The PPS has also been modelled by a 12 fixed knot cubic Hermite polynomial and estimated from CMB and WiggleZ data, together with measurements of $\sigma_8$ from CFHTLenS and the Planck Sunyaev-Zeldovich catalogue [14]. In [15] the Planck data was used to constrain a linear spline PPS with 1 movable knot, while a 3 fixed knot cubic spline was used in [16].

There have been far fewer non-parametric approaches. The Planck team have most recently used a penalised likelihood inversion method involving a B-spline for the PPS [12]; a similar scheme with a 485 knot cubic spline had been used earlier for their first data release [17]. Another example is the inversion of Planck data with Richardson-Lucy deconvolution [18]. An attractive method called PRISM which uses a ‘sparsity’ prior on features in the PPS in a wavelet basis to regularise the inverse problem was developed in [19] and has been subsequently applied to Planck data [20].

In the alternative approach we follow here the background parameters are held fixed, which permits the deconvolution of the smoothing kernel relating the observables to the PPS in linear cosmological perturbation theory. We have refined our earlier method and now use the logarithm of the power spectra in the reconstruction which ensures that the recovered spectra are positive, and allows us to set priors on the slope of the spectra. Moreover we correct for gravitational lensing of the CMB which is important on the small scales probed by the latest experiments. Our method features a ‘regularisation parameter’ $\lambda$ that balances the influence on the solution of prior information with that of the observed data. By studying the trade-off between the resolution and stability of the recovered PPS we find $\lambda = 400$ and 20000 to be suitable values for the regularisation parameter (see figure 18, appendix B). We have no criterion for choosing between them, so present results for both values.

We confirm that all the features we identified previously [2] in WMAP data are also present in the Planck data at $\gtrsim 2\sigma$ confidence. Moreover there is a new feature at $k$/Mpc$^{-1} \sim$
0.12–0.15 at 4σ confidence for λ = 400 (2.9σ for λ = 20000), even after we take out the 217x217 GHz data from Planck. We did so following the suggestion [22] that there are residual systematics in this particular channel, which was confirmed by the Planck collaboration in their updated paper [9]. This both illustrates the problems in reliably identifying features, but it also makes more compelling the need for further detailed studies. Reliable detection of even one feature in the spectrum would immediately rule out all slow-roll models of inflation. Hence this is a key probe of inflation, complementary to searches for non-gaussianity and gravitational waves (see [23] and extensive references therein to inflationary models which generate features in the PPS).

2 Inversion method

2.1 Tikhonov regularisation

Let us assume there are N available cosmological data sets, each with N_sub data points d_a(Z), from which we wish to estimate the PPS. Here the subscript runs from 1 to N_sub and the superscript Z denotes the data set. In a flat (or open) universe, the points of many data sets are related to the power spectrum P_ζ(k) of the curvature perturbation ζ [21] by

\[ d_a(Z) = \int_0^\infty K_a(Z, k) P_ζ(k) dk + n_a(Z). \]  

Here the integral kernels K_a(Z, k) depend on the background cosmological parameters θ, and the noise vectors n_a(Z) have zero mean and covariance matrices N_{ab} \equiv ⟨n_a(Z)n_b(Z)⟩. In what follows we also include in θ extraneous ‘nuisance’ parameters associated with the likelihood functions of the data sets, such as calibration parameters or the parameters describing the CMB foregrounds. We assume an estimate ˆθ of the background and nuisance parameters exists which is independent of the N data sets, and has a zero mean uncertainty u, with elements u_α. Then ⟨u_αn_a(Z)⟩ = 0 for all elements of the uncertainty and noise vectors as these are uncorrelated by assumption. The covariance matrix for the estimated background parameters is just U \equiv ⟨uu^T⟩, where ^T signifies the matrix transpose. Given our estimate of the background and nuisance parameter set ˆθ, the goal is to obtain an estimate ˆP_ζ(k) of the PPS from the data sets.

The PPS is approximated as a piecewise function given by a sum of N_j basis functions φ_i(k), weighted by coefficients p_i:

\[ P_ζ(k) = \sum_{i=1}^{N_j} p_i φ_i(k). \]  

For a grid of wavenumbers \{k_i\} the basis functions are defined as

\[ φ_i(k) \equiv \begin{cases} 1, & k_i < k \leq k_{i+1}, \\ 0, & \text{elsewhere}. \end{cases} \]

We use a logarithmically spaced grid between k_1 = 7 × 10^{-6} Mpc^{-1} and k_{N_j+1} = 30 Mpc^{-1} with N_j = 2500. Substituting eq. (2.2) into eq. (2.1) gives

\[ d_a(Z) = \sum_i W_{ai}^{(Z)}(θ) p_i + n_a(Z). \]
where the \( N_Z \times N_j \) matrices \( W^{(Z)}_{ai} (\theta) \) depend on the background parameters:

\[
W^{(Z)}_{ai} (\theta) = \int_{k_i}^{k_{i+1}} K^{(Z)}_a (\theta, k) \, dk.
\]

(2.5)

As discussed in [2] solving eq. (2.1) for the PPS is an ill-posed inverse problem and the matrices \( W^{(Z)}_{ai} \) are ill-conditioned. Consequently naïve attempts to determine the PPS by maximising the likelihood function \( \mathcal{L} (p, \theta | d) \) of the data \( d \) given \( p \) and \( \theta \) produce ill-behaved spectra with wild irregular oscillations. To overcome this, Tikhonov regularisation [1] uses a penalty function \( R (p) \) which takes on large values for unphysical spectra. Then the likelihood is maximised subject to the constraint that the penalty function at most equals a certain value \( R_0 \):

\[
\max_p \mathcal{L} (p, \theta | d) \ \text{subject to} \ R (p) \leq R_0.
\]

(2.6)

Rather than working directly with \( p \) we use instead \( y \) with elements \( y_i = \ln p_i \) in order to enforce the positivity constraint on the recovered PPS. Thus the estimated PPS is given by

\[
y \left( d, \hat{\theta}, \lambda \right) = \min_y Q \left( y, d, \hat{\theta}, \lambda \right),
\]

(2.7)

where

\[
Q \left( y, d, \hat{\theta}, \lambda \right) \equiv L \left( y, \hat{\theta}, d \right) + \lambda R (y).
\]

(2.8)

Here \( L (p, \theta, d) \equiv -2 \ln \mathcal{L} (p, \theta | d) \) and the regularisation parameter \( \lambda \) acts as a Lagrange multiplier.

Since to a first approximation the PPS is a power-law with a constant spectral index \( n_s - 1 = d \ln P_{\zeta} / d \ln k \) [21], we use the penalty function

\[
R (y) = \sum_{i=1}^{N_k-1} \left[ y_{i+1} - y_i - (n_s - 1) \Delta \ln k \right]^2,
\]

\[
\propto \int \left( \frac{d \ln P_{\zeta}}{d \ln k} - n_s + 1 \right)^2 d \ln k,
\]

(2.9)

(2.10)

where \( \Delta \ln k \) is the logarithmic separation of the \( \{ k_i \} \) wavenumber grid. Using the \( (N_k - 1) \times N_k \) first difference matrix \( L \) and the \( N_k \times N_k \) matrix \( \Gamma \) given by

\[
L = \begin{pmatrix}
-1 & 1 \\
-1 & 1 \\
\vdots & \vdots \\
-1 & 1 \\
\end{pmatrix}, \quad \Gamma \equiv L^T L = \begin{pmatrix}
1 & -1 & -1 \\
-1 & 2 & -1 \\
-1 & 2 & -1 \\
\vdots & \vdots & \vdots \\
-1 & 1 & 1
\end{pmatrix},
\]

(2.11)

together with the \( N_k - 1 \) vector \( \eta \) with elements \( \eta_i \equiv (n_s - 1) \Delta \ln k \) the penalty function can be written as

\[
R (y) = y^T \Gamma y - 2 \eta^T L y + \eta^T \eta.
\]

(2.12)

It penalises large excursions and conservatively smooths the estimated PPS towards a power-law of amplitude set by the data and a ‘prior’ spectral index \( n_s \). The penalty function determines the way in which the recovered PPS is smoothed, while the regularisation parameter
controls the amount of smoothing. Thus \( \hat{y} \) depends on \( \lambda \) and \( R \), and both must be chosen carefully to give sensible results. The pseudo Newton-Raphson algorithm of [2] is again employed to minimise \( Q \) and estimate the PPS.

In our previous work [2] following tests using mock data we performed reconstructions with \( \lambda = 100 \) and \( \lambda = 5000 \). We desire comparable results in this paper, but are now working with the logarithmic elements \( y_i = \ln p_i \) instead of \( p_i \) in the inversion. For data sets with Gaussian likelihood functions, 

\[
\frac{\partial \hat{y}_i}{\partial d_a(Z)} \propto \left[ \sum_{Z,a,b} W^{(Z)}_{ia} \left( N^{(Z)} \right)^{-1} W^{(Z)}_{jb} p_j + \lambda \Gamma_{ij} \right]^{-1}
\]

in the logarithm-based reconstruction, whereas 

\[
\frac{\partial \hat{p}_i}{\partial d_a(Z)} \propto \left[ \sum_{Z,a,b} W^{(Z)}_{ia} \left( N^{(Z)} \right)^{-1} W^{(Z)}_{jb} + \lambda \Gamma_{ij} \right]^{-1}
\]

in the non-logarithmic case. As a result the regularisation parameter must be a factor of \( p_i^2 \approx 4 \) (in units of \( 10^{-9} \)) larger for a logarithmic reconstruction to approximate a non-logarithmic one. Hence we now use \( \lambda = 400 \) and \( 20000 \). As shown in figure 18 of appendix B these values provide a close to optimal compromise between the resolution and the variance of the reconstruction. The higher value in general yields smoother spectra, however we have no rationale for choosing one value over the other so present our results using both values.

2.2 CMB lensing

After last scattering CMB photons are gravitationally deflected by large scale structure. This CMB lensing smooths the acoustic peaks of the temperature and polarisation angular power spectra, and also generates B-mode polarisation on small scales. ACT, SPT and Planck have all detected CMB lensing at high significance assuming a power-law PPS [24–26]. Since lensing changes the TT spectrum by around 20% at \( \ell = 3000 \) it must be taken into account in order to obtain an accurate PPS reconstruction.

The deflection angle equals the gradient of the lensing potential \( \psi \), which is given by a weighted integral of the gravitational potential along the line of sight. The power spectrum of the lensing potential \( s_\psi^\ell = \ell (\ell + 1) C_\psi^\ell / 2\pi \) can be written as [27]

\[
s_\psi^\ell = \int_0^\infty K_\psi^\ell (\theta, k) P_\zeta (k) \, dk.
\]

We include the effects of nonlinear structure formation in the kernel \( K_\psi^\ell \) using the Halofit [46] fitting formula for the nonlinear matter power spectrum in the same way as [28], but applied with a fixed fiducial PPS. Substituting eq. (2.2) into the above equation gives 

\[
s_\psi^\ell = \sum_i W_\psi^\ell p_i.
\]

Two quantities which characterise the statistical properties of the deflection angle are

\[
\sigma^2 (r) = \sum_\ell \frac{\ell^2}{\ell + 1} \left[ 1 - J_0 (\ell r) \right] s_\psi^\ell,
\]

\[
C_{gl,2} (r) = \sum_\ell \frac{\ell^2}{\ell + 1} J_2 (\ell r) s_\psi^\ell,
\]

where \( J_0 \) and \( J_2 \) are Bessel functions.

The predicted CMB angular power spectra \( \ell (\ell + 1) C^I_\ell / 2\pi \) where \( I \in \{ \text{TT}, \text{TE}, \text{EE}, \text{BB} \} \) are denoted \( s^I_\ell \). The unlensed scalar temperature power spectrum is \( s_{\ell,s}^{\text{TT}} = \sum_i W_{\ell,i,s}^{\text{TT}} p_i \), where the scalar matrix \( W_{\ell,i,s}^{\text{TT}} \) is calculated from the scalar temperature integral kernel as in eq. (2.5). In the Boltzmann code CAMB used for this work the total lensed temperature power spectrum is \( s^{\text{TT}}_\ell = s_{\ell,s}^{\text{TT}} + s_{\ell,\ell}^{\text{TT}} \). Here the lensed scalar TT
Figure 1. Left: comparison of the spectra recovered with λ = 400 from the Planck, WMAP-9 polarisation, ACT and SPT data, with and without correcting for gravitational lensing. Right: the fractional change $(\hat{P}_\zeta^{\text{No-Lens}}(k) - \hat{P}_\zeta(k)) / \hat{P}_\zeta(k)$ in the recovered PPS due to the lensing correction.

The spectrum $\tilde{s}_{TT}$ is related to the unlensed spectrum by $\tilde{s}_{TT} = \sum_{\ell'} W_{\ell'\ell}^{TT} s_{TT}^{\ell'}$ in the perturbative ‘flat-sky’ approximation of [29, 30], where

$$ W_{\ell'\ell}^{TT} = \frac{\ell (\ell + 1)}{\ell' + 1} \int_0^\pi e^{-\ell'^2 \sigma^2(r)/2} J_0(\ell r) \left[ J_0(\ell' r) + \frac{\ell'^2}{2} C_{\text{gl},2}(r) J_2(\ell' r) \right] r \, dr. \tag{2.16} $$

To obtain $\hat{y}$ by minimising $Q$ we need the derivative

$$ \frac{\partial L_{\text{CMB}}}{\partial y_i} = \sum_{\ell'} \frac{\partial L_{\text{CMB}}}{\partial s_{TT}^{\ell'}} \left( W_{\ell'\ell}^{TT} W_{\ell'i}^{TT} + \sum_{\ell''} \frac{\partial W_{\ell'\ell}^{TT}}{\partial s_{TT}^{\ell''}} W_{\ell''i}^{TT} \right) p_i. \tag{2.17} $$

Here $L_{\text{CMB}}$ is the sum of the ACT, SPT and Planck likelihood functions, and

$$ \frac{\partial W_{\ell'\ell}^{TT}}{\partial s_{TT}^{\ell''}} = \frac{\ell (\ell + 1) \ell'^2}{(\ell' + 1) (\ell'' + 1)} \int_0^\pi e^{-\ell'^2 \sigma^2(r)/2} J_0(\ell r) \left\{ J_2(\ell' r) J_0(\ell' r) - [1 - J_0(\ell' r)] J_0(\ell r) + \frac{\ell'^2}{2} C_{\text{gl},2}(r) J_2(\ell' r) \right\} r \, dr. \tag{2.18} $$

The derivative $\partial L_{\text{CMB}} / \partial s_{TT}^{\ell}$ is a function of $s_{TT}$, which is calculated from $\tilde{s}_{TT}$ at each iteration of the Newton-Raphson minimisation algorithm using the more accurate but complicated curved-sky correlation function method of [28] as implemented in CAMB. The effect of the lensing correction is shown in figure 1. Since lensing smooths the acoustic peaks, neglecting it means that fitting the data requires spurious oscillatory features in the recovered PPS on small scales. Including the lensing correction removes these spurious features.

Lensing of the EE and TE spectra is neglected as it has a negligible effect for the data sets considered here. Thus $s_{TT}^{EE} = s_{TT}^{EE} + s_{TT}^{EE}$ where $s_{TT}^{EE} = \sum_i W_{\ell_i,t}^{EE} p_i$ and $s_{TT}^{EE} = \sum_i W_{\ell_i,t}^{EE} q_i$, and similarly for the TE spectrum.

3 Results

We choose a standard $\Lambda$CDM model when performing the reconstructions. The background cosmological and foreground parameter values, which are quite consistent with those obtained by the Planck team [9] are listed in table 1.
| Parameter type | Parameter | Value | Parameter type | Parameter | Value |
|----------------|-----------|-------|----------------|-----------|-------|
| Cosmological   | $\Omega_b h^2$ | 0.02240 | ACT + SPT | $A_{143}^{PS,ACT}$ | 11.93 |

Table 1. Parameter values used when performing the reconstructions. The cosmological parameters were obtained by a fit to data combination IV, assuming a power-law spectrum.

The inversion method is applied to the following 5 combinations of data sets:

- Data combination I: Planck + WMAP-9 polarisation
- Data combination II: Combination I + ACT + SPT
- Data combination III: Combination II + WiggleZ + galaxy clusters
- Data combination IV: Combination III + CFHTLenS weak lensing + VHS Lyman-α data

The data sets and their likelihood functions are discussed in appendix A. Throughout we use a prior of $n_s = 0.969$ in the scalar penalty function (2.12), corresponding to the best-fit power-law PPS to data combination IV.

The scalar PPS found from the Planck and WMAP-9 polarisation data exhibits a number of interesting deviations from a power-law, as shown in figures 2 and 3. For $k \lesssim 0.03$ Mpc$^{-1}$ the PPS is similar to that recovered from the WMAP-9 temperature angular power spectrum in [2]. As in the earlier reconstruction, there is a cutoff on large scales from the low TT quadrupole followed by dips at $k \simeq 0.0018$, 0.0070 and 0.013 Mpc$^{-1}$ due to a
Figure 2. Primordial power spectra recovered from data combinations I to IV involving the Planck, WMAP-9 polarisation, ACT, SPT, WiggleZ, galaxy clustering, CFTHLenS and Lyman-α data, with $\lambda = 400$, compared to the best-fit power-law spectrum (slope $n_s = 0.969$, magenta dashed line). In all panels the central black line is the reconstruction adopting this $n_s$ value as a prior, and the dark band is the 1σ error given by the square root of the diagonal elements of the Bayesian covariance matrix $\Sigma$ (B.22), while the smaller light band is similarly obtained from the frequentist covariance matrix $\Pi$ (B.20). Vertical lines delineate the wavenumber range covered by the resolution kernels (see figure 16) over which the reconstruction is faithful to the true PPS, while the horizontal lines indicate the wavenumber range over which specific datasets have most impact.

deficit in power around the $\ell \approx 22, 90$ and 180 multipoles of the Planck TT spectrum, and peaks at $k \approx 0.0034$ and 0.0088 Mpc$^{-1}$ due to the excess power around the $\ell \approx 40$ and 120 multipoles. A peak at $k \approx 0.027$ Mpc$^{-1}$ and dips at $k \approx 0.032$ and 0.039 Mpc$^{-1}$ correspond to the excess around $\ell \approx 370$ and the deficits around $\ell \approx 410$ and 540 respectively. A deficit around $\ell \approx 800$ causes a dip at $k \approx 0.057$ Mpc$^{-1}$. Peaks at $k \approx 0.10$ and 0.12 Mpc$^{-1}$ and a dip at $k \approx 0.105$ Mpc$^{-1}$ originate from the excesses around $\ell \approx 1350$ and 1600 and the deficit around $\ell \approx 1450$ respectively. We exclude the $217 \times 217$ GHz cross-spectrum for $1700 < \ell < 1860$ because these multipoles are known to be contaminated by electromagnetic interference from the 4K Joule-Thomson cryogenic cooler, as discussed in appendix A.1. Hence the dip found at $k \approx 0.14$ Mpc$^{-1}$ arises from the deficit around $\ell \approx 1800$ in the $143 \times 217$ GHz cross-spectrum alone and is presumably uncontaminated.

Adding the ACT and SPT observations improves the reconstruction over the range $0.08 \lesssim k \lesssim 0.28$ Mpc$^{-1}$. A deficit around $\ell \approx 2450$ introduces a dip at $k \approx 0.19$ Mpc$^{-1}$. Including the WiggleZ and galaxy cluster data, which cover $0.02 \lesssim k \lesssim 0.25$ Mpc$^{-1}$, deepens the dips at $k \approx 0.032$ Mpc$^{-1}$ and $k \approx 0.19$ Mpc$^{-1}$. The reconstruction is extended to
smaller scales by the weak lensing and Lyman-α measurements, which together span 0.01 \( \lesssim k \lesssim 2.0 \text{ Mpc}^{-1} \). The spectra in figure 3 recovered with \( \lambda = 20000 \) are suppressed for \( k \lesssim 0.003 \text{ Mpc}^{-1} \) due to the deficit at \( \ell \simeq 22 \). The dip at \( k \simeq 0.14 \text{ Mpc}^{-1} \) is the most significant.

The Planck, ACT, SPT and WiggleZ data derived from the recovered spectra are compared to the measured data in figure 4 to figure 7. The ‘running average’ is defined over \( n \) data points (\( n \) odd) as: \( \delta a_{\lambda}^{(\ell)} \equiv \frac{1}{n} \sum_{b=-(n-1)/2}^{(n-1)/2} a_{\lambda+b} \). The residuals after subtracting the TT spectrum of the best-fit \( n_8 = 0.969 \) PPS from that of the reconstructed spectra are shown in figure 5, together with the \( \ell = 31 \) running average of the Planck data residuals. In each case the predicted data match the measurements well. However, the predicted CFHTLenS \( \xi_{+}(\theta) \) shear correlation is systematically higher than the data, as seen in figure 8. This is consistent with the tension between CFHTLenS and Planck for a power-law PPS that has been reported in the literature, the cause of which is an open question at present [9, 31–34]. Planck is known to favour a slightly higher value of \( \sigma_8 \) than galaxy cluster abundance observations [35, 55]. Here for \( \lambda = 500 \) the galaxy cluster parameter is \( \Sigma_8 \equiv \sigma_8 (\Omega_m/0.27)^{0.3} = 0.809 \), while \( \Sigma_8 = 0.808 \) for \( \lambda = 20000 \). This is higher than, but not inconsistent with, the value \( \Sigma_8 = 0.797 \pm 0.05 \) obtained by the cluster abundance observations listed in appendix A.5.

The VHS Lyman-α data is consistent with the CMB, WiggleZ and galaxy cluster data for a calibration parameter \( A = 0.54 \), a 1.9\( \sigma \) deviation from the expected value of unity. This is in agreement with [36] which found that the VHS data for \( A = 1 \) is approximately a factor of 2 higher than expected from the WMAP-3 results.

The large-scale cutoff, \( k \simeq 0.0018 \text{ Mpc}^{-1} \) dip and \( k \simeq 0.0034 \text{ Mpc}^{-1} \) peak have been observed in model-independent PPS estimates since the release of the WMAP-1 data [23].
Figure 4. Fits to the $\ell < 50$ Planck TT data (residuals) of primordial power spectra recovered with $\lambda = 400$ (full blue line) and $20000$ (dashed red line) from the Planck, WMAP-9 polarisation, ACT, SPT, WiggleZ, galaxy clustering, CFTHLenS and Lyman-\(\alpha\) data (combination IV). The residuals are obtained by subtracting off the TT spectrum of the best-fit $n_s = 0.969$ power-law spectrum.

Our data combination I reconstruction with $\lambda = 400$ is clearly consistent with the PPS found from the $50 \leq \ell \leq 2500$ data by the Planck team using their penalised likelihood method [17]. Similar features can be seen at e.g. $k \simeq 0.027$, 0.057, 0.12 and 0.14 Mpc$^{-1}$. The latter three fluctuations were also emphasised in the Richardson-Lucy deconvolution study [18].

3.1 Background and nuisance parameter errors

To demonstrate how errors in the background and nuisance parameters affect the recovered PPS, we calculate the covariance matrix $\Sigma_P$ (B.21) using the error matrix

$$
\Sigma_P = \text{diag} \left[ (0.012 \omega_b)^2, (0.022 \omega_c)^2, (0.018 h)^2, (0.15 \tau)^2, (0.03 b)^2, (0.53 A)^2,
(0.061 A_{220}^{PS, SPT})^2, (0.026 r_{150 \times 220}^{PS})^2, (0.2 r_{95 \times 220}^{PS})^2, (0.11 r_{95 \times 150}^{PS})^2, (0.056 A_{148}^{PS, ACT})^2,
(0.24 A_{100}^{PS})^2, (0.089 r_{143 \times 217}^{PS})^2, (0.06 A_{218}^{PS, ACT})^2, (0.051 A_{150}^{PS, SPT})^2, (0.1 A_{217}^{CIB})^2,
(0.59 A_{143}^{SZ})^2 \right].
$$

(3.1)

Here some selected nuisance parameters associated with the CMB foregrounds $f_\ell$ defined in appendix A are included. These errors correspond to the uncertainties in the parameter values obtained from the Planck, ACT, SPT and WiggleZ data assuming a power-law PPS.$^1$

The effect of the foreground parameter uncertainties on the diagonal elements of the matrix $\Sigma_P$ is shown in figure 9. The contribution of the foregrounds $f_\ell$ to the total TT angular power spectrum increases with the multipole moment $\ell$. Hence the error due to uncertainties in the foreground parameters is greatest at $k \simeq 0.25$ Mpc$^{-1}$, which is approximately the smallest scale probed by the CMB data. As discussed in detail in [2], the patterns of peaks on intermediate scales in figure 10 is due to the effects of uncertainties in the background parameters propagating through the CMB acoustic peaks. The Sachs-Wolfe plateau is more

---

$^1$Although our analysis assumes that the data sets used to estimate the background and nuisance parameters are different from those used to recover the PPS, the parameter error matrix is used merely as an example.
Figure 5. Comparison of residuals for the $\ell = 31$ running average of the Planck data (orange line) with the residuals corresponding to the $\lambda = 400$ (full blue line) and $\lambda = 20000$ (red dashed line) reconstructions from the Planck, WMAP-9 polarisation, ACT, SPT, WiggleZ, galaxy clustering, CFHTLenS and Lyman-\alpha data (combination IV). The band indicates the 1\sigma scatter of the $\ell = 31$ running average data, calculated from the Planck covariance matrix. Top left: 100 GHz data. Top right: 143 GHz data. Bottom left: 217 GHz data (the vertical strip indicates the unused $1700 < \ell < 1860$ multipoles). Bottom right: 143 \times 217 GHz data.

Our understanding of the recovered PPS is complicated by the correlation between neighbouring PPS elements due to the smoothing criterion. To overcome this we calculate uncorrelated bandpowers which represent the independent degrees of the freedom of the reconstruction using the method of [2]. Correlated bandpowers (with a non-diagonal frequentist covariance matrix $\Sigma_N$) are transformed into uncorrelated bandpowers (with a diagonal covariance matrix) by multiplication with a set of window functions. These are the rows of the Hermitian square root of $\Sigma_N^{-1}$, normalised to sum to unity. The effective number of free parameters of the reconstruction is estimated by the quantity $\nu_1 \equiv \sum_{Z, i, a} W_{ni}^{(Z)} M_{ia}^{(Z)}$. Since $\nu_1 = 56.5$
Figure 6. Fit to data from ACTs (top left), ACTe (top right), 95, 95 × 150, 95 × 220 GHz SPT (bottom left) and 150, 150 × 220, 220 GHz SPT (bottom right) of power spectra recovered with \( \lambda = 400 \) and 20000 from the Planck, WMAP-9 polarisation, ACT, SPT, WiggleZ, galaxy clustering, CFTHLenS and Lyman-\( \alpha \) data (combination IV). The 95 × 150 and 95 × 220 GHz SPT spectra have been shifted vertically (respectively by 250 and 500 \( K^2 \)) for clarity.

Figure 7. Fit to WiggleZ data (in 4 redshift bins) of power spectra recovered with \( \lambda = 400 \) and 20000 from the Planck, WMAP-9 polarisation, ACT, SPT, WiggleZ, galaxy clustering, CFTHLenS and Lyman-\( \alpha \) data (combination IV), convolved with the WiggleZ window functions. Both data and theoretical predictions have been averaged over the 7 sky regions and shifted vertically for clarity (by a factor of 0.4, 0.6, 0.8 and 1.2 respectively for \( z = 0.22, 0.41, 0.60 \) and 0.78).
Figure 8. Fit to CFHTLenS shear correlation data $\xi_+ (\theta)$ (top left) and $\xi_- (\theta)$ (top right), and Lyman-\(\alpha\) data from LUQAS (bottom left) and Croft (bottom right), of power spectra recovered with $\lambda = 400$ and 20000 from the Planck, WMAP-9 polarisation, ACT, SPT, WiggleZ, galaxy clustering, CFHTLenS and Lyman-\(\alpha\) data (combination IV). The $\xi_- (\theta)$ measurement at $\theta = 212'$ is negative (indicated by a dashed error bar).

for $\lambda = 400$ and $\nu_1 = 16.85$ for $\lambda = 20000$ we choose 57 bandpowers for $\lambda = 400$ and 17 bandpowers for $\lambda = 20000$. The correlated bandpowers are chosen so that the window functions are as well-behaved and non-negative as possible. Figures 11 and 12 show the window functions and uncorrelated bandpowers. The window functions are lower and less localised at the wavenumbers corresponding to the troughs of the CMB angular power spectrum, where the resolution is reduced.

3.3 Statistical significance of the features

We need to establish if the features in the PPS reconstructions are consistent with noise-induced artifacts or if they represent genuine departures of the true PPS from a power-law. We perform a hypothesis test with the null hypothesis being that the true spectrum is the best-fit power-law to data combination IV, which has $n_s = 0.969$, and invert $10^6$ mock data realisations generated using the null hypothesis PPS. The $\ell < 50$ CMB data points were simulated by sampling a Wishart distribution as in [2], while the other data points were drawn from Gaussian distributions with the correct covariance matrices. The distribution of the results is compared to the reconstruction from the real data in figure 13, which gives a visual indication of the statistical significance of the features in the reconstruction. The mean of the recovered spectra is biased low on large scales with $\lambda = 400$ due to the non-Gaussian CMB likelihood function for low multipoles, as in [2].
Figure 9. Contributions of some CMB foreground parameters to the square root of the diagonal elements of the matrix \( \Sigma_F \) (B.21) for Planck, WMAP-9 polarisation, ACT, SPT, WiggleZ, galaxy clustering, CFTHLenS and Lyman-\( \alpha \) data (combination IV), with \( \lambda = 400 \) and 20000. The error contributions are added in quadrature.

Figure 10. Contributions of different background parameters to the square root of the diagonal elements of the matrix \( \Sigma_F \) (B.21) for data combination IV (Planck, WMAP-9 polarisation, ACT, SPT, WiggleZ, galaxy clustering, CFTHLenS, Lyman-\( \alpha \)) with \( \lambda = 400 \) (left) and 20000 (right). The error contributions are added in quadrature. In both panels the red line is the square root of the diagonal elements of the matrix \( \Sigma_F \) (B.20) and is included for comparison. The black line is the square root of the diagonal elements of the matrix \( \Sigma \) (B.19) and includes contributions to the total error from uncertainties in the background and nuisance parameters, as well as from noise in the data.
Figure 11. Bandpower window functions for $\lambda = 400$, 20000 of reconstructions with data combination IV (Planck, WMAP-9 polarisation, ACT, SPT, WiggleZ, galaxy clustering, CFTHLenS, Lyman-\textalpha{}).

Figure 12. Decorrelated bandpowers for $\lambda = 400$ and 20000. The black line is the PPS recovered from data combination IV (Planck, WMAP-9 polarisation, ACT, SPT, WiggleZ, galaxy clustering, CFTHLenS, Lyman-\textalpha{)}. The light band is the 1$\sigma$ error obtained from the square root of the diagonal elements of the frequentist covariance matrix $\Sigma_F$ (B.20). The vertical error bars are the 1$\sigma$ errors given by the diagonal bandpower covariance matrix. The horizontal error bars indicate the locations of the 25th and 75th percentiles of the absolute value of the bandpower window functions.

Figure 13. Comparison of the PPS (full black line) recovered using data combination IV (Planck, WMAP-9 polarisation, ACT, SPT, WiggleZ, galaxy clustering, CFTHLenS, Lyman-\textalpha{}) with the results of $10^6$ simulated reconstructions for $\lambda = 400$ and 20000 which were generated using a power-law PPS with $n_s = 0.969$ (dashed blue line). The shaded bands indicate the 1$\sigma$ and 2$\sigma$ error estimate from Monte Carlo simulations, while the red dot-dashed line is the mean of the reconstructions.
To assess the evidence against the null hypothesis at a particular wavenumber $k$ we use the local test statistic

$$T(k) \equiv \sum_i \frac{(\hat{p}_i - p_i^{PL})^2}{\sigma_i^2} \phi_i(k).$$

(3.2)

Here $\sigma_i^2$ is the variance of $\hat{p}_i - p_i^{PL}$, the deviation of the estimated PPS $\hat{p}_i$ from the null hypothesis power-law PPS $p_i^{PL}$ at wavenumber bin $i$. For a given wavenumber we compute the $p$-value of $T(k)$ (the probability under the null hypothesis of exceeding the observed test statistic value) using the distribution of $T(k)$ in the $10^6$ simulated inversions.\(^2\) The wavenumbers with the lowest $p$-values are recorded in tables 2 and 3.

For $\lambda = 400$ the peak at $k \simeq 0.12 \text{ Mpc}^{-1}$ represents a $4\sigma$ excursion, while the $k \simeq 0.057 \text{ Mpc}^{-1}$ dip and the $k \simeq 0.10 \text{ Mpc}^{-1}$ peak constitute $2.7\sigma$ and $2.8\sigma$ deviations respectively. All the other features have less than $2.4\sigma$ significance, including the dip at $k \simeq 0.0018 \text{ Mpc}^{-1}$ associated with the $\ell \simeq 22$ power deficit and the dip at $k \simeq 0.14 \text{ Mpc}^{-1}$ where the unreliable 217 GHz Planck spectrum is omitted. The statistical significance of the features in the $\lambda = 20000$ reconstruction is generally lower. The greatest departure from a power-law is the $k \simeq 0.14 \text{ Mpc}^{-1}$ dip at $2.9\sigma$, up from $2.0\sigma$ for $\lambda = 400$.

While the $T(k)$ statistic can be used to gauge the significance of an individual feature, it must be remembered that over a sufficiently large wavenumber interval the $T(k)$ $p$-value will be small at some $k$ purely by chance even if the null hypothesis is true. This is an example of the ‘look-elsewhere’ effect [37, 38], or the problem of multiple comparisons, which is that the likelihood of a false detection of an anomaly increases with the size of parameter space searched. To account for this effect we use the global test statistic

$$T_{\text{max}} \equiv \max_k T(k),$$

(3.3)

\(^2\)On small scales where the CMB likelihood is Gaussian, the $T(k)$ statistic is $\chi^2$ distributed to a high degree of accuracy.

| $k/\text{Mpc}^{-1}$ | 0.00177 | 0.0272 | 0.0390 | 0.0573 | 0.101 |
|---------------------|---------|---------|---------|---------|-------|
| $p$-value | 0.0291 | 0.0219 | 0.0364 | 0.00674 | 0.00471 |
| Stat.sig./$\sigma$ | 2.18 | 2.29 | 2.09 | 2.71 | 2.83 |

Table 2. $T(k)$ $p$-values of the highest significance features in the PPS recovered from data combination IV with $\lambda = 400$. The $p$-values are also converted to equivalent two-sided Gaussian standard deviations to express the statistical significance.

| $k/\text{Mpc}^{-1}$ | 0.105 | 0.119 | 0.140 | 0.202 | 0.223 |
|---------------------|-------|-------|-------|-------|-------|
| $p$-value | 0.0203 | $5.40 \times 10^{-5}$ | 0.0474 | 0.0207 | 0.0304 |
| Stat.sig./$\sigma$ | 2.32 | 4.04 | 1.98 | 2.71 | 2.83 |

Table 3. Same as table 2, but for $\lambda = 20000$. 

| $k/\text{Mpc}^{-1}$ | 0.0639 | 0.0873 | 0.0999 | 0.117 | 0.140 |
|---------------------|-------|-------|-------|-------|-------|
| $p$-value | 0.0902 | 0.140 | 0.100 | 0.0231 | 0.00398 |
| Stat.sig./$\sigma$ | 1.69 | 1.47 | 1.64 | 2.27 | 2.88 |
equal to the maximum value of $T(k)$ over the wavenumber range of the recovered PPS. Clearly if there are significant features anywhere in the PPS, $T_{\text{max}}$ will be greater than expected under the null hypothesis. The $T_{\text{max}}$ $p$-value for the most significant feature at $k \simeq 0.12$ Mpc$^{-1}$, again computed using the simulations, is 0.0239 for $\lambda = 400$ and 0.172 for $\lambda = 20000$. This is equivalent to 2.26$\sigma$ and 1.37$\sigma$ respectively, hence both reconstructions of the scalar perturbations are statistically consistent with a power-law and there is no significant evidence presently for features in the PPS.

4 Conclusions

The generation of large-scale structure in the universe by growth of initially small density fluctuations through gravitational instability is akin to a scattering experiment at a high energy accelerator. The ‘beam’ here corresponds to the primordial perturbations, the ‘target’ to the (mainly dark) matter content of the universe, and the ‘detector’ to the universe as a whole, while the ‘signal’ is the CMB anisotropy or galaxy correlations. In contrast to the laboratory situation where the only unknown is the physical interaction between the beam and the target, in the cosmological context this is known to be gravity. However all else is unknown or uncertain. We cannot simultaneously infer the properties of the target and the detector with an unknown beam, hence there are ‘degeneracies’ and necessarily circularity in e.g. inferring cosmological parameters (the ‘detector’) or the nature of the dark matter (the ‘target’) or the spectrum of the density fluctuations (the ‘beam’). It is common in particular for the spectrum to be taken to be a power-law and the dark matter to be cold and collisionless, in determining the parameters of the assumed ΛCDM cosmology.

A crucial consistency check is to reverse this procedure and attempt to infer the PPS, as we have done following our method detailed earlier [2], using Planck [3] and other CMB and large-scale structure data sets. We find several features in the spectrum, of which one has significance $\simeq 4\sigma$ for $\lambda = 400$ ($\simeq 2.9\sigma$ for $\lambda = 20000$). This is potentially of great interest as such features cannot be generated in the standard slow-roll models of inflation driven by a scalar field. However the feature is suspect (even though it is in the supposedly clean 143x217 GHz spectrum) as it is associated with the same multipole range 1700 $< \ell <$ 1860 as the 217x217 GHz contamination. Hence we cannot claim that it is primordial in origin. In addition its significance drops to $\sim 2\sigma$ after we account for the ‘look elsewhere’ effect, hence there is presently no compelling evidence for a departure of the scalar fluctuations from a power-law spectrum.

Nevertheless we believe that searches for spectral features are still the best direct probe of inflation, especially given the lack of evidence for any non-gaussianity in the CMB and the well recognised difficulties in searches for the B-mode polarisation signal from inflationary gravitational waves. In contrast to the latter signatures, the TT signal is orders of magnitude higher, with systematics that can in principle be better understood. Hence we intend to continue such searches with further data releases from Planck and other CMB experiments, as well as data from observational probes of large-scale structure in the universe, which can be consistently analysed together in our framework.

Acknowledgments

We acknowledge use of the CAMB and cosmoMC codes and thank the Planck team for making their data and analysis tools publicly available. PH is grateful to the Niels Bohr Institute for hospitality and SS acknowledges a DNRF Niels Bohr Professorship. We thank Pavel Naselsky for very helpful discussions.
A Data sets

We discuss the data sets used in our analysis; throughout we have treated the data exactly as recommended by the experimental collaboration which provided it.

A.1 Planck

The Planck temperature likelihood function $L_{\text{Planck}}$ is a hybrid combination of a Gibbs sampler based Blackwell-Rao estimator $L_{\text{Comm}}$ implemented in the Commander software code for $2 \leq \ell \leq 49$, and a Gaussian pseudo-$C_\ell$ approximation $L_{\text{CamSpec}}$ for $50 \leq \ell \leq 2500$ computed by the CamSpec code [3]. Thus $L_{\text{Planck}} = L_{\text{Comm}} + L_{\text{CamSpec}}$. The Commander likelihood uses a low-resolution, foreground-cleaned combination of the seven maps from 30 to 353 GHz, while the CamSpec likelihood uses cross-spectra from the 100, 143 and 217 GHz channels. The multipole range for the 100 × 100 GHz and 143 × 143 GHz spectra is $50 \leq \ell \leq 1200$ and $50 \leq \ell \leq 2000$ respectively, while the 217 × 217 GHz and 143 × 217 GHz spectra both cover $500 \leq \ell \leq 2500$. The CamSpec likelihood is [41]

$$L_{\text{CamSpec}} = \sum_{\ell\ell'} \sum_{II'} \left( \frac{s_{TT}^{II} + t_{TT}^{II'}}{\sigma_{TT}^{II'}} - d_{TT}^{II'} \right) \left( N_{\ell\ell'}^{-1} \right) \left( \frac{s_{TT}^{II'} + t_{TT}^{II'}}{\sigma_{TT}^{II'}} - d_{TT}^{II'} \right),$$

(A.1)

where the index $I$ labels the spectrum, i.e. $I \in \{100 \times 100, 143 \times 143, 217 \times 217, 143 \times 217\}$. Here $s_{TT}^{II}$ is the theoretical temperature angular power spectrum and $d_{TT}^{II}$ is the measured $I$th cross-spectrum. The covariance matrices $N_{\ell\ell'}^{-1}$ incorporate the correlations between the different spectra and are evaluated for a fixed fiducial model. The $t_{TT}^{II}$ terms represent the unresolved ‘foreground’ which can include galactic point sources, clustered sources in the cosmic infrared background (CIB), and the kinetic and thermal Sunyaev-Zeldovich effects (kSZ and tSZ) from galaxy clusters, as discussed in [3, 9]. They are given by

$$f_{100\times 100}^{143\times 143} \equiv A_{143}^{100} A_{143}^{143} + A_{143}^{kSZ\times tSZ} + c_1 A_{143}^{tSZ \times tSZ} + c_2 A_{143}^{kSZ \times tSZ} + c_3 A_{143}^{tSZ \times tSZ} + \gamma_c \tilde{CIB},$$

(A.2)

$$f_{143\times 143}^{143\times 143} \equiv A_{143}^{143} A_{143}^{143} + A_{143}^{kSZ\times kSZ} + c_2 A_{143}^{tSZ \times tSZ} + c_3 A_{143}^{kSZ \times tSZ} + c_4 A_{143}^{tSZ \times tSZ} + \gamma_c \tilde{CIB},$$

(A.3)

$$f_{217\times 217}^{143\times 143} \equiv A_{217}^{143} A_{217}^{143} + A_{217}^{kSZ\times kSZ} + c_4 A_{217}^{tSZ \times tSZ} + \gamma_c \tilde{CIB},$$

(A.4)

$$f_{143\times 217}^{143\times 217} \equiv A_{143}^{143} A_{217}^{143} + A_{143}^{kSZ\times kSZ} + c_3 A_{143}^{tSZ \times tSZ} + \gamma_c \tilde{CIB},$$

(A.5)

where $\tilde{CIB}$ is the amplitudes and cross-correlations of the various foreground components. Beam and calibration errors are responsible for the following terms in the likelihood:

$$\sigma_{TT}^{II} = C_I \left( 1 + \beta_{100\times 100}^{143\times 143} \sum_i q_i E_i^{100} \right)^{-1}. $$

(A.6)
Figure 14. The PPS recovered from the Planck data with (red line) and without (black line) the 217 GHz data over the 1700 < \ell < 1860 multipoles, with \( \lambda = 400 \) (left) and \( \lambda = 20000 \) (right). The orange line is the PPS recovered from the 217 GHz 1500 < \ell < 2060 multipoles alone, while the dashed magenta line is the best-fit power-law with \( n_\nu = 0.969 \). Removing the contaminated 217 GHz data does reduce the amplitude of the peak at \( k = 0.14 \) Mpc\(^{-1} \) feature, but it still remains significant.

Here \( C_I \) are the calibration factors for the different spectra, with \( C_{143\times143} = 1 \) and \( C_{143\times217} = C_{217\times217}^{1/2} \), so that only \( C_{100\times100} \) and \( C_{217\times217} \) are free parameters. Uncertainties in the beam transfer functions are parameterised by the beam error eigenmodes \( E_{i\ell}^I \) [42]. All of the beam eigenmode amplitudes apart from \( \beta_{100\times100}^I \) (the first of the 100 \times 100 beam eigenmodes) are marginalised over analytically. This gives rise to the second factor above where \( g_i^T \) are the beam conditional means, with \( g_{100\times100}^T = 1 \).

Electromagnetic interference between the Planck satellite 4K Joule-Thomson cryogenic cooler and the HFI bolometers produces discrete ‘lines’ in the power spectral density of the time-ordered data, which manifest as features at certain multipoles in the measured angular power spectrum [43]. As first suggested in [22] and later confirmed by the Planck team [9], the correction for the 4K cooler lines was imperfect, leading to an artifical dip at \( \ell \approx 1800 \) in the 217 \times 217 GHz cross-spectrum. We therefore exclude the 217 \times 217 GHz data over the interval 1700 < \ell < 1860 when performing our reconstructions. Figure 14 shows that the effect of removing the data is to reduce the amplitude of the peak at \( k = 0.12 \) Mpc\(^{-1} \) and the dip at \( k = 0.14 \) Mpc\(^{-1} \) in the recovered PPS.

Both the derivative \( \partial L_{\text{Comm}} / \partial y_i \), which is evaluated numerically, and the Hessian \( \partial^2 L_{\text{Comm}} / \partial y_i \partial y_j \) are required in order to obtain \( \hat{y} \). Now, for \( \ell < 50 \) we use the expression

\[
(N_{TT})_{i\ell}^{-1} = \frac{(2\ell + 1) f_{\text{sky}}^2}{2 (s_{\ell}^{TT} + N_{\ell}^{TT})^2},
\]

for the diagonal elements of the inverse TT covariance matrix, where \( f_{\text{sky}} = 0.8 \) is the effective fraction of the sky covered by Planck. To estimate the TT noise spectrum we employ

\[
\frac{1}{N_{\ell}^{TT}} = \sum_{\nu} \frac{1}{(\Delta T^\nu_{\ell \nu}^T)^2} \exp \left[ -\frac{\ell (\ell + 1) \theta_\nu}{8 \ln 2} \right],
\]

valid for an idealised CMB experiment with Gaussian beams and isotropic Gaussian white noise. Here \( \nu \) is the frequency of the band, \( \theta_\nu \) is the beam width and \( \Delta T^T_{\ell \nu} \) is the temperature noise per pixel. Following [62] we include only the 3 channels (100, 143 and 217 GHz) least affected by foreground contamination and assume they have been perfectly cleaned.
Their specifications are listed in Table 4. The subdominant off-diagonal elements of the covariance matrix are neglected. The Hessian is then approximated by

$$\Delta_{i,j}^{TT} \simeq 2 \sum_{\ell'} W_{ij} W_{\ell' j} \left( N_{TT}^{-1} \right)_{\ell \ell'} W_{\ell j},$$

which holds for a Wishart (or Gaussian) likelihood function.

We do not do any further processing of the maps such as imposing a mask/apodization or ‘inpainting’. This may well be necessary to remove possibly spurious features especially at high \(\ell\), but we consider that this is best done by the Planck Collaboration themselves.

### A.2 ACT

ACT measures CMB anisotropies at frequencies including 148 and 218 GHz in two separate regions of the sky — an equatorial strip (ACTe) and a southern strip (ACTs) [4, 44]. Hence the total likelihood is

$$L_{\text{ACT}} = L_{\text{ACTe}} + L_{\text{ACTs}}$$

(A.9)

Here \(I \in \{148 \times 148, 148 \times 218, 218 \times 218\}\) labels the three cross-frequency pairs used in the likelihood. ACT measured bandpowers (labelled \(b\)) in bands of multiple \(\ell\), with window functions \(W_{bb'}\), thus \(s_{bb'}^I = \sum_{\ell} W_{bb'}^I W_{\ell bb'}^{TT}\). The 148 × 148 GHz bandpowers lie in the range 1000 ≤ \(\ell\) ≤ 3250, while the 148 × 218 and 218 × 218 GHz bandpowers cover 1500 ≤ \(\ell\) ≤ 3250. We do not use higher multipole bandpowers as secondary CMB anisotropies dominate over the PPS-dependent primary anisotropies on such small scales. ACTe (ACTs) data was collected over two (three) seasons of observations, hence the bandpower measurements \(d_{\ell \alpha}^b\) are labelled both by pairs of seasons (the index \(\alpha\)) and pairs of frequencies (the index \(I\)). For ACTe there are three different season pairs for the 148 × 148 and 218 × 218 GHz bandpowers, and four season pairs for the 148 × 218 GHz bandpowers, leading to a total of 10 bandpower sets. For ACTs there are 21 bandpower sets as there are six season pairs for the 148 × 148 and 218 × 218 GHz bandpowers, and nine season pairs for the 148 × 218 GHz bandpowers.

The ACT foreground model is the same as the one used for Planck, therefore

\[
\begin{align*}
\tilde{f}_{148}^{148,148} &= A_{148}^{\text{PS, ACT}} \tilde{\ell}^2 + A_{148}^{\text{PS, ACT}} t_{148} + c_5 A_{148}^{\text{PS, ACT}} t_{148} + c_6 A_{148}^{\text{CIB}} \tilde{\ell}^{CIB} \\
&+ c_{7} A_{\text{dust}}^{\text{ACTe}} \tilde{\ell}^{-0.7} - 2 c_6 \left( c_5 A_{148}^{\text{CIB}} \right)^{1/2} t_{148}^{CIB} t_{\text{dust}}^{\text{CIB}}, \\
\tilde{f}_{148}^{218} &= A_{148}^{\text{PS, ACT}} \tilde{\ell}^2 + A_{148}^{\text{PS, ACT}} t_{148} + c_5 A_{148}^{\text{PS, ACT}} t_{148} + c_6 A_{148}^{\text{CIB}} \tilde{\ell}^{CIB} \\
&+ c_{7} A_{\text{dust}}^{\text{ACTe}} \tilde{\ell}^{-0.7} - 2 c_6 \left( c_5 A_{148}^{\text{CIB}} \right)^{1/2} t_{148}^{CIB} t_{\text{dust}}^{\text{CIB}}, \\
\tilde{f}_{218}^{218} &= A_{218}^{\text{PS, ACT}} \tilde{\ell}^2 + A_{218}^{\text{PS, ACT}} t_{218} + c_5 A_{218}^{\text{PS, ACT}} t_{218} + c_6 A_{218}^{\text{CIB}} \tilde{\ell}^{CIB} + c_{7} A_{\text{dust}}^{\text{ACTe}} \tilde{\ell}^{-0.7}. \\
\end{align*}
\]

(A.10)

### Table 4

| \(\nu/\text{GHz}\) | \(\theta_{\nu}\) | \(\Delta_{i,j}^{TT}/\mu\text{K}\) |
|-----------------|-----------------|-------------------|
| 100             | 9.6'            | 8.2               |
| 143             | 7.0'            | 6.0               |
| 217             | 4.6'            | 13.1              |

The specifications are listed for the 100, 143 and 217 GHz channels of the Planck HFI [63].
The extra terms proportional to $\ell^{-0.7}$ represent a residual ‘Galactic cirrus’ contribution [9].

The constants $c_4$ to $c_9$ correspond to scalings of the foreground parameters between the Planck and ACT effective frequencies. The calibration factors are $\sigma^{148\times148} = (y^{\text{ACTe/s}}_{148})^2$, $\sigma^{148\times218} = y^{\text{ACTe/s}}_{148} y^{\text{ACTe/s}}_{217}$ and $\sigma^{218\times218} = (y^{\text{ACTe/s}}_{217})^2$ where $y^{\text{ACTe/s}}_{148}$ and $y^{\text{ACTe/s}}_{218}$ are the map-level calibration parameters for ACTe and ACTs. Beam errors are included in the covariance matrices $N^{ll'}_{bb\alpha\alpha'}$ [9].

### A.3 SPT

SPT mapped the CMB anisotropies at 95, 150 and 220 GHz. Following the Planck team only the data reported in [45] is used. The SPT likelihood is

$$L_{\text{SPT}} = \sum_{b'} \sum_{ll'} \left( \frac{s_{ll'}^b}{\sigma_{ll'}} - d_{ll'}^b \right) \left( N_{bb'}^{-1} \right)^{ll'} \left( \frac{s_{ll'}^{b'}}{\sigma_{ll'}} - d_{ll'}^{b'} \right),$$

(A.13)

where $I \in \{95 \times 95, 95 \times 150, 95 \times 220, 150 \times 150, 150 \times 220, 220 \times 220\}$ labels the cross-power spectra. We use the bandpowers $s_{ll'}^b = \sum_{\ell} W_{ll'}^{b} s_{TT}^{\ell}$ in the range $2000 \leq \ell \leq 3250$. The foreground bandpowers are $f_{ll'}^b = \sum_{\ell} W_{ll'} f_{\ell}^{b}$ where

$$f_{95\times95}^{\ell} = A_{95}^{\text{PS, SPT}} \ell + A_{95}^{\text{tSZ}} k_{95} + c_{10} A_{95}^{\text{CIB}} A_{95}^{\text{tSZ}} + c_{11} \bar{\ell}^{-1.2},$$

(A.14)

$$f_{95\times150}^{\ell} = A_{95}^{\text{PS, SPT}} A_{150}^{\text{PS, SPT}} \ell^{1/2} + A_{95}^{\text{tSZ}} k_{150} + c_{12} A_{95}^{\text{CIB}} A_{150}^{\text{tSZ}} + (c_{11} c_{13})^{1/2} \bar{\ell}^{-1.2} - c_{14} (c_{10} A_{143}^{\text{CIB}} A_{150}^{\text{tSZ}})^{1/2} \bar{\ell}^{1/2} \bar{\ell}^{-1.2},$$

(A.15)

$$f_{95\times220}^{\ell} = A_{95}^{\text{PS, SPT}} A_{220}^{\text{PS, SPT}} \ell^{1/2} + A_{95}^{\text{tSZ}} k_{220} + (c_{11} c_{13})^{1/2} \bar{\ell}^{-1.2} - c_{16} (c_{10} A_{143}^{\text{CIB}} A_{220}^{\text{tSZ}})^{1/2} \bar{\ell}^{1/2} \bar{\ell}^{-1.2},$$

(A.16)

$$f_{150\times150}^{\ell} = A_{150}^{\text{PS, SPT}} \ell + A_{150}^{\text{tSZ}} k_{150} + c_{17} A_{150}^{\text{CIB}} A_{150}^{\text{tSZ}} + c_{14} A_{150}^{\text{CIB}} \bar{\ell}^{1/2} \bar{\ell}^{-1.2} + c_{13} \bar{\ell}^{-1.2} - 2c_{14} (c_{17} A_{143}^{\text{CIB}} A_{150}^{\text{tSZ}})^{1/2} \bar{\ell}^{1/2} \bar{\ell}^{-1.2},$$

(A.17)

$$f_{150\times220}^{\ell} = A_{150}^{\text{PS, SPT}} A_{220}^{\text{PS, SPT}} \ell^{1/2} + A_{150}^{\text{tSZ}} k_{220} + (c_{11} c_{16} c_{13})^{1/2} \bar{\ell}^{1/2} \bar{\ell}^{-1.2} - c_{16} (c_{17} A_{217}^{\text{CIB}} A_{150}^{\text{tSZ}})^{1/2} \bar{\ell}^{1/2} \bar{\ell}^{-1.2},$$

(A.18)

$$f_{220\times220}^{\ell} = A_{220}^{\text{PS, SPT}} \ell + A_{220}^{\text{tSZ}} k_{220} + c_{15} \bar{\ell}^{-1.2}.$$

(A.19)

The $\ell^{-1.2}$ terms originate from Galactic dust emission [9]. The calibration uncertainties are related to the map-level calibration parameters $y_{95}^{\text{SPT, SPT}}$, $y_{150}^{\text{SPT, SPT}}$ and $y_{220}^{\text{SPT, SPT}}$ through

$$\sigma^{95\times95} = (y_{95}^{\text{SPT, SPT}})^2, \quad \sigma^{95\times150} = y_{95}^{\text{SPT, SPT}} y_{150}^{\text{SPT, SPT}}, \quad \sigma^{95\times220} = y_{95}^{\text{SPT, SPT}} y_{220}^{\text{SPT, SPT}}, \quad \sigma^{150\times150} = (y_{150}^{\text{SPT, SPT}})^2, \quad \sigma^{150\times220} = y_{150}^{\text{SPT, SPT}} y_{220}^{\text{SPT, SPT}} \quad \text{and} \quad \sigma^{220\times220} = (y_{220}^{\text{SPT, SPT}})^2 [9].$$

### A.4 WiggleZ

The WiggleZ galaxy redshift survey measured the galaxy power spectrum $P_{\text{gal}}(k)$ using the photometric redshift estimates of $1.7 \times 10^5$ galaxies over seven regions of the sky in four redshift bins centred at $z = \{0.22, 0.41, 0.60, 0.78\}$, with a total volume of $\sim 1$ Gpc$^3$. In what follows the index $I$ labels the redshift bin and the index $r$ labels the sky region. To obtain the
theoretical galaxy power spectrum at each redshift we use the ‘N-body simulation calibrated without damping’ method recommended by the WiggleZ team [6], so that

$$P_{\text{gal}}(k) \equiv b^2 \frac{P_{\text{it}}^{\text{fid}}(k)}{P_{\text{it}}(k)} \frac{P_{\text{poly}}(k)}{P_{\text{hf}}^{\text{fid}}(k)} \frac{P_{\zeta}(k)}{P_{\text{fid}}(k)} P_{\text{it}}^{-1}(k).$$

(A.20)

Here $P_{\zeta}(k)$ is a power-law fit in the wavenumber range $0.01 < k < 0.3$ Mpc$^{-1}$ to the PPS recovered at each iteration of the Newton-Raphson minimisation, and $P_{\text{hf}}^{\text{fid}}(k)$ is the Halofit [46] fitting formula for the nonlinear matter power spectrum at redshift $I$ corresponding to $P_{\zeta}(k)$. Hence on small scales where nonlinear effects are negligible, $P_{\text{it}}^{\text{fid}}(k)/P_{\zeta}(k)$ equals $T^2(k)$, the square of the linear matter transfer function. The power-law fit is used because it is unclear how to apply the Halofit formula to matter power spectra with localised features. The factor $P_{\text{poly}}(k)/P_{\text{hf}}^{\text{fid}}(k)$ accounts for additional nonlinear and redshift space distortion effects specific to WiggleZ, as determined from the GiggleZ N-body simulations. The quantity $P_{\text{it}}^{\text{fid}}(k)$ is the Halofit nonlinear matter power spectrum at redshift $I$ for the GiggleZ fiducial cosmological model, and $P_{\text{poly}}(k)$ is a fifth-order polynomial fit to the GiggleZ power spectrum at redshift $I$.

The galaxy power spectrum $P_{\text{gal}}(k)$ is related to $d_{a}^{Ir}$, the $a$th power spectrum measurement in the $r$th region at the $I$th redshift, by a convolution with a window function $W_{a}^{Ir}(k)$ that depends on the WiggleZ survey geometry. As in our previous paper [2] we transform the window function into $W_{a}^{Ir}(k) \equiv (\gamma^{I})^{-2} W_{a}^{I} (\gamma^{I} k)$ to account for the fact that the mapping from redshift space to real space depends on the assumed cosmological model. Here the ‘Alcock-Paczynski scaling factor’ $\gamma^{I}$ is

$$\gamma^{I} \equiv \left[ \frac{(D_{A}^{I})^2 H_{\text{fid}}^{I}}{(D_{A,fid}^{I})^2 H^{I}} \right]^{1/3},$$

(A.21)

where $D_{A}^{I}$ is the angular diameter distance and $H^{I}$ is the Hubble parameter, both at the $I$th redshift, and the subscript ‘fid’ refers to the quantities for the fiducial model assumed by the WiggleZ team. The WiggleZ data points are then

$$d_{a}^{Ir} = \int_{0}^{\infty} W_{a}^{Ir}(k) P_{\text{gal}}(k) \, dk + n_{a}^{Ir},$$

(A.22)

where $n_{a}^{Ir}$ is an additive noise term. Using 2.2 and A.20 gives $s_{a}^{Ir} = \sum_{i} W_{ai}^{Ir} p_{i}$. The likelihood function has the Gaussian form

$$L_{\text{WiggleZ}} = \sum_{a} \sum_{Ir} (s_{a}^{Ir} - d_{a}^{Ir}) (N_{aa}^{-1})^{Ir} (s_{a'}^{Ir} - d_{a'}^{Ir}).$$

(A.23)

Note that the different redshift bins and the sky regions are uncorrelated.

### A.5 Galaxy clusters

The variance of the matter density contrast smoothed over a scale $R$ using the top-hat filter $F(x) = 3 (\sin x - x \cos x)/x^3$ is

$$\sigma_{R}^2 = \frac{1}{2\pi^2} \int F^2 (kR) P_{m}(k) k^2 \, dk.$$
Observations of galaxy cluster abundance, when fitted to semi-analytic predictions for the halo mass function, constrain the combination $\sigma_8 \Omega_m^q$ where $q \approx 0.4$ [53, 54]. In [55] the Planck collaboration compiled the results of 5 recent galaxy cluster experiments and presented them in their table 2 as constraints on the quantity $\bar{\sigma}_8 = \sigma_8 (\Omega_m/0.27)^{0.3}$.

The Chandra Cluster Cosmology Project (CCCP) used X-ray observations of 49 nearby ($z < 0.2$) and 37 distant ($0.4 < z < 0.9$) galaxy clusters to obtain $\bar{\sigma}_8 = 0.784 \pm 0.027$ [56]. The clusters were first detected by the ROSAT satellite and then reobserved with the Chandra satellite. From 10810 clusters of the optically selected SDSS MaxBCG catalogue, which lie in the range $0.1 < z < 0.3$, Rozo et al. found $\bar{\sigma}_8 = 0.806 \pm 0.033$ [57]. In the likelihood analyses of the CCCP and MaxBCG data, $\omega_b$ and $n_s$ were held fixed at values consistent with the WMAP5 results. In the MaxBCG analysis the hubble parameter was set to $h = 0.7$, while a prior on $h$ derived from Hubble Space Telescope (HST) observations was applied in the CCCP analysis.

A collection of 15 SZ clusters in the range $0.2 < z < 1.4$ detected with the Sunyaev-Zel dovich (SZ) effect by ACT with optical follow-up observations gave $\Sigma_8 = 0.848 \pm 0.032$ [58]. This measurement neglects the uncertainty in the SZ scaling relation parameters, which were held fixed at values taken from a certain gas pressure profile model. The Planck collaboration found $\bar{\sigma}_8 = 0.764 \pm 0.025$ using 189 high signal-to-noise clusters from the Planck SZ catalogue with redshifts up to $z = 1$, when the hydrostatic mass bias was allowed to vary between zero and 30%. If the bias was fixed at the best-fit value from numerical simulations of 20% then $\Sigma_8 = 0.78 \pm 0.01$ [55]. A study of 698 clusters at redshift $z < 0.5$ from the REFLEX II X-ray catalogue using X-ray luminosity as a mass proxy derived $\Sigma_8 = 0.80 \pm 0.03$ [59]. It held most of the other cosmological parameters fixed at values consistent with the WMAP9 and Planck CMB results. Using 100 SZ clusters in the range $0.3 < z < 1.4$ identified by SPT (of which 63 had optical velocity dispersion measurements and 16 had X-ray observations from either Chandra or the XMM-Newton satellite), [60] reported $\Sigma_8 = 0.809 \pm 0.036$. Both the ACT and SPT analyses employed priors from Big Bang Nucleosynthesis (BBN) and HST data, while Planck used BBN and Baryonic Acoustic Oscillations (BAO) constraints instead.

The scatter in the $\Sigma_8$ measurements is greater than the quoted errors, which indicates the presence of unknown systematic errors. We summarise the measurements as $\Sigma_8 = 0.797 \pm 0.050$ and use this in our work. The likelihood function for galaxy clusters is

$$L_{GC} = \frac{(s - d)^2}{\sigma^2}.$$  \hspace{1cm} (A.25)

Here $d = (0.27/\Omega_m)^{0.6} \Sigma_8^2$, $\sigma$ is the uncertainty in $d$ and $s = \sum_i W_i p_i$, where $W_i$ is derived from eq. (A.24).

**A.6 CFHTLenS**

The Canada-France-Hawaii Telescope Lensing Survey (CFHTLenS) covers an area of 154 square degrees in five optical bands. The two-point cosmic shear correlation functions $\xi_+ (\theta)$ and $\xi_- (\theta)$ were estimated from the ellipticity and photometric redshift measurements of 4.2 million galaxies in the redshift range $0.2 < z < 1.3$. Two-point shear statistics are related to the convergence power spectrum $P_\kappa (\ell)$, which is given by a weighted integral of the matter power spectrum $P_m (k, z)$ along the line of sight [51, 52]:

$$P_\kappa (\ell) = \frac{9 \Omega_m^2 H_0^4}{4 c^4} \int_0^{\chi_H} \frac{g^2 (\chi)}{a^2 (\chi)} P_m \left[ \frac{\ell}{D_A (\chi)} z (\chi) \right] d\chi.$$  \hspace{1cm} (A.26)
Here the radial comoving distance of a source at redshift \( z \), \( \chi_H \) denotes the horizon distance and \( a(\chi) \) is the scale factor at a distance \( \chi \). The comoving angular diameter distance \( D_A(\chi) \) out to a distance \( \chi \) depends on the curvature of the universe:

\[
D_A(\chi) = \begin{cases} 
  cH_0^{-1} \Omega_K^{-1/2} \sinh \left( \Omega_K^{1/2} c^{-1} H_0 \chi \right) & \text{for } \Omega_K > 0 \\
  \chi & \text{for } \Omega_K = 0 \\
  cH_0^{-1} |\Omega_K|^{-1/2} \sin \left( |\Omega_K|^{1/2} c^{-1} H_0 \chi \right) & \text{for } \Omega_K < 0 .
\end{cases}
\]

The lensing efficiency function \( g(\chi) \) is defined as

\[
g(\chi) = \int_{\chi}^{\chi_H} \rho \left[ z \left( \chi' \right) \right] \frac{dz}{\chi'} \frac{D_A(\chi' - \chi)}{D_A(\chi')} d\chi',
\]

where \( \rho(z) \) is the redshift distribution of the source galaxies normalised to unity,

\[
\int_0^\infty \rho \left( z \right) dz = 1 .
\]

The shear correlation functions are Hankel transforms of the convergence power spectrum,

\[
\xi_{+/−}(\vartheta) = \frac{1}{2\pi} \int_0^\infty J_{0/4} (\ell \vartheta) P_\kappa (\ell) \ell d\ell ,
\]

where \( \xi_+ \) and \( \xi_- \) correspond to \( J_0 \) and \( J_4 \) respectively, Bessel functions of the first kind of order 0 and 4. Using the substitution \( k = \ell / D_A(\chi') \) this can be rewritten as

\[
\xi_{+/−}(\vartheta) = \int_0^\infty \mathcal{K}_{+/−}(\theta, \vartheta, k) P_\zeta(k) dk .
\]

Here the integral kernels are

\[
\mathcal{K}_{+/−}(\theta, \vartheta, k) = \frac{9 \Omega_m^2 H_0^4}{8 \pi c^4} \int_0^{\chi_H} \frac{D_A^2(\chi) g^2(\chi)}{a^2(\chi)} J_{0/4} (k D_A(\chi) \vartheta) \frac{P_\zeta^h([k, z(\chi)])}{P_\zeta^h(k)} k d\chi ,
\]

where \( P_\zeta^h(k) \) is a power-law fit in the wavenumber range \( 0.01 < k < 0.3 \) Mpc\(^{-1}\) to the PPS recovered at each iteration of the Newton-Raphson minimisation, and \( P_\zeta^h(k, z) \) is the Halofit nonlinear matter power spectrum corresponding to \( P_\zeta^h(k) \). We exclude angular scales for which nonlinear evolution alters the shear correlation functions by more than 20%. Thus \( \xi_+ \) and \( \xi_- \) data points are retained for \( \vartheta > 12 \) arc min and \( \vartheta > 53 \) arc min respectively, as \( \xi_- \) is more sensitive to nonlinear effects than \( \xi_+ \).

Denoting the observed values and the theoretical predictions of \( \xi_{+/−}(\vartheta_a) \) by \( \delta_a^\mu \) and \( s_a^\mu \) respectively, the likelihood function is

\[
L_{CFHTens} = \sum_{a \mu} \sum_{a' \nu} \left( s_a^\mu - d_a^\mu \right) \left( N_{aa'}^{-1} \right)^{\mu \nu} \left( s_{a'}^\nu - d_{a'}^\nu \right) .
\]

Here \( a \) and \( a' \) label the angular scale while \( \mu \) and \( \nu \) stand for the ‘+’ and ‘−’ components. The covariance matrix \( N_{aa'}^{\mu \nu} \) was calculated for a fiducial model.
A.7 Lyman-\(\alpha\) data

VHS [8] used Lyman-\(\alpha\) forest observations by Croft [47] and LUQAS (Large Sample of UVES QSO Absorption Spectra) [48] to estimate the linear matter power spectrum on scales \(0.3 \, h/\text{Mpc} \lesssim k \lesssim 3 \, h/\text{Mpc}\). The LUQAS sample consists of 27 high-resolution quasar spectra taken by the UVES spectrograph on the Very Large Telescope. The Croft sample comprises 30 high-resolution and 23 low-resolution spectra obtained using the HIRES and LRIS instruments of the Keck observatory. The mean absorption redshift of the Croft and LUQAS samples is \(z_{\text{Croft}} \simeq 2.72\) and \(z_{\text{LUQAS}} \simeq 2.25\). VHS employed the so-called ‘effective bias’ method [49] calibrated by a suite of hydrodynamical simulations to infer the matter power spectrum from the transmitted flux power spectrum of the two datasets. The VHS results were subsequently incorporated into the CosmoMC module 1ya.f90 [50].

The Lyman-\(\alpha\) likelihood is

\[
L_{\text{Ly} \alpha} = L_{\text{Croft}} + L_{\text{LUQAS}}
\]

(A.35)

Here \(s_a\) and \(d_a\) are the theoretical and measured matter power spectrum data points respectively, \(\sigma_a^2\) is the variance of the uncorrelated measurement errors and \(A = 1 \pm 0.29\) is the overall calibration error of the effective bias method. The latter originates mainly from uncertainties in the numerical simulations, the effective optical depth, the mean temperature of the intergalactic medium and the slope of the temperature-density relation. The factor

\[
Q_{\Omega}^{\text{Croft/LUQAS}} = \left[ \frac{2.4}{1 + 1.4 \Omega_m^{0.6} (z_{\text{Croft/LUQAS}})} \right]^2
\]

(A.36)

accounts for the dependence of the inferred matter power spectrum on the matter density \(\Omega_m\) at the redshift of the Lyman-\(\alpha\) data.

A.8 WMAP9 polarisation

The pixel-based WMAP9 polarisation likelihood \(L_{WP}\) covers \(\ell \leq 23\) and uses the WMAP9 polarisation maps at 33, 41 and 61 GHz. The Planck team updated the temperature map used in constructing the likelihood to the Planck Commander map. Our handling of this data set is the same as in our previous paper [2].

B Error analysis

When generalised to include perturbative nonlinear effects eq. (2.1) becomes

\[
d_a^{(Z)} = c_a^{(Z)}(\theta) + \int_0^\infty K_a^{(Z)}(\theta, k) P_\zeta(k) \, dk
+ \int_0^\infty \int_0^\infty K_a^{(Z)}(\theta, k_1, k_2) P_\zeta(k_1) P_\zeta(k_2) \, dk_1 \, dk_2 + n_a^{(Z)},
\]

(B.1)

which is valid in the mildly nonlinear regime. Using the expansion eq. (2.2) gives

\[
d_a^{(Z)} = c_a^{(Z)}(\theta) + \sum_i W_{ai}^{(Z)}(\theta) \, p_i + \frac{1}{2} \sum_{ij} S_{aij}^{(Z)}(\theta) \, p_i p_j + n_a^{(Z)},
\]

(B.2)
where
\[ S_{aij}^{(Z)}(\theta) = \int_{k_i}^{k_{i+1}} \int_{k_j}^{k_{j+1}} k_a^{(Z)}(\theta, k_1, k_2) \, dk_1 \, dk_2. \] (B.3)

We emphasise that the additional nonlinear terms are \textit{not} used elsewhere in this paper but are included here for completeness.

Any deconvolution method for recovering the PPS defines a transfer function \( T \) which gives the relationship of the estimate \( \hat{y} \) to the true PPS \( y_{\text{tru}} \). It depends on the true background parameters \( \theta_{\text{tru}} \), the estimated background parameters \( \hat{\theta} \) and the noise in the data \( n \) so that
\[ \hat{y}(d, \hat{\theta}) = T(y_{\text{tru}}, \theta_{\text{tru}}, \hat{\theta}, n). \] (B.4)

Performing a Taylor expansion of \( T \) about a fiducial PPS \( y_{\text{fid}} \) close to \( y_{\text{tru}} \) yields
\[ \hat{y}_i(d, \hat{\theta}) = T_i(y_{\text{fid}}, \theta_{\text{tru}}, \theta_{\text{tru}}, 0) + \sum_j R_{ij} \Delta y_j + \frac{1}{2} \sum_{j,k} Y_{ijkl} \Delta y_j \Delta y_k \]
\[ + \sum_{a} M_{ia} n_a \, + \sum_{\alpha} M_{ia} u_\alpha + \sum_{a,\alpha} Z_{ija} n_a \, + \sum_{a,\alpha} Z_{ija} u_\alpha \]
\[ + \frac{1}{2} \sum_{a,b} X_{iab} n_a n_b + \sum_{a} X_{iaa} n_a u_a + \frac{1}{2} \sum_{\alpha,\beta} X_{iab} u_a u_\beta \] \[ \text{(B.5)} \]

Here \( \Delta y_i \equiv y_{\text{tru}} - y_{\text{fid}} \),
\[ M_{ia} = \frac{\partial^2 \hat{y}_i}{\partial d_a^{(Z)} \partial d_b^{(Z)}}, \quad X_{iab} = \frac{\partial^2 \hat{y}_i}{\partial d_a^{(Z)} \partial d_b^{(Z)}}, \]

where \( d_{\text{fid}} \) denotes collectively the datasets estimated from \( y_{\text{fid}} \), i.e.
\[ \hat{d}_{\text{fid}} = d_{\text{fid}}^{(Z)}(\theta_{\text{tru}}) + \sum_{t} W_{at}^{(Z)}(\theta_{\text{tru}}) \hat{p}_{\text{fid}}^t + \frac{1}{2} \sum_{ij} S_{aij}^{(Z)}(\theta_{\text{tru}}) \hat{p}_{\text{fid}}^i \hat{p}_{\text{fid}}^j, \] (B.6)
and
\[ R_{ij} = \sum_{a,k} M_{ia}^{(Z)} W_{aj}^{(Z)}(\theta_{\text{tru}}) p_j + \sum_{a,k} M_{ia} S_{ajk}^{(Z)}(\theta_{\text{tru}}) p_j p_k, \] (B.7)
\[ Y_{ijkl} = \sum_{a,b,k} X_{iab}^{(Z)} W_{aj}^{(Z)}(\theta_{\text{tru}}) W_{bk}^{(Z)}(\theta_{\text{tru}}) p_j p_k + \sum_{a,k} M_{ia} S_{ajk}^{(Z)}(\theta_{\text{tru}}) p_j p_k, \]
\[ + \sum_{a,b,l} X_{iab}^{(Z)} S_{ajl}^{(Z)}(\theta_{\text{tru}}) W_{bk}^{(Z)}(\theta_{\text{tru}}) p_j p_k p_l + \delta_{jk} \sum_{a,k} M_{ia} W_{aj}^{(Z)}(\theta_{\text{tru}}) p_k, \]
\[ + \sum_{a,b,l} X_{iab}^{(Z)} W_{aj}^{(Z)}(\theta_{\text{tru}}) S_{bkf}^{(Z)}(\theta_{\text{tru}}) p_j p_k p_l + \delta_{jk} \sum_{a,k} M_{ia} S_{ajl}^{(Z)}(\theta_{\text{tru}}) p_k p_l, \]
\[ + \sum_{a,b,l,m} X_{iab}^{(Z)} S_{ajl}^{(Z)}(\theta_{\text{tru}}) S_{bkm}^{(Z)}(\theta_{\text{tru}}) p_j p_k p_m. \] (B.8)
These matrices characterise the inversion and are discussed in more detail in [2]. In particular the sensitivity matrices \( M_{ia}^{(Z)} \) give the dependence of the estimated PPS on the data points \( d_k^{(Z)} \). They control the manner in which noise in the data produces artifacts in the recovered PPS. The first-order resolution matrix \( R \) describes the linear mapping from \( y_{\text{tru}} \) to \( y \). The closer \( R \) is to the identity matrix \( I \), the better the resolution and the lower the bias of the inversion method. For Tikhonov regularisation \( \sum_j R_{ij} \approx 1 \) for all \( i \) so that the estimated PPS is correctly scaled. The second-order resolution matrix \( \Sigma \) details a quadratic mapping of \( y_{\text{tru}} \) to \( \hat{y} \) and should vanish in order to minimise the bias. For Tikhonov regularisation analytic expressions for these inversion matrices can be derived as in [2]:

\[
M_{ia}^{(Z)} = -\sum_j A_{ij}^{-1} B_{j\alpha}^{(Z)}, \quad M_{ia} = -\sum_j A_{ij}^{-1} B_{j\alpha}, \tag{B.9}
\]

\[
X_{ia}^{(Z)} = \sum_{j,k,l} A_{ij}^{-1} C_{jkl}^{(Z)} M_{ka}^{(Z)} - \sum_{j,k} A_{ij}^{-1} E_{jka}^{(Z)} M_{ka}^{(Z)} - \sum_{j} A_{ij}^{-1} D_{j\alpha}^{(Z)}, \tag{B.10}
\]

\[
X_{iaa}^{(Z)} = -\sum_{j,k,l} A_{ij}^{-1} C_{jkl}^{(Z)} M_{ka} M_{ka} - \sum_{j,k} A_{ij}^{-1} E_{jka} M_{ka} - \sum_{j} A_{ij}^{-1} D_{j\alpha}, \tag{B.12}
\]

\[
X_{iab}^{(Z)} = -\sum_{j,k,l} A_{ij}^{-1} C_{jkl}^{(Z)} M_{ka} M_{ka} - \sum_{j,k} A_{ij}^{-1} E_{jka} M_{ka} - \sum_{j} A_{ij}^{-1} D_{j\alpha}, \tag{B.13}
\]

\[
A_{ij} = \left. \frac{\partial^2 Q}{\partial y_i \partial y_j} \right|_{\hat{y}_{\text{fid}}, \hat{d}_{\text{fid}}, \theta_{\text{tru}}}, \quad B_{ia} = \left. \frac{\partial^2 Q}{\partial y_i \partial \theta_{\alpha}} \right|_{\hat{y}_{\text{fid}}, \hat{d}_{\text{fid}}, \theta_{\text{tru}}}, \quad C_{ijk} = \left. \frac{\partial^3 Q}{\partial y_i \partial y_j \partial y_k} \right|_{\hat{y}_{\text{fid}}, \hat{d}_{\text{fid}}, \theta_{\text{tru}}}, \quad D_{ia} = \left. \frac{\partial^2 Q}{\partial y_i \partial \hat{d}_a} \right|_{\hat{y}_{\text{fid}}, \hat{d}_{\text{fid}}, \theta_{\text{tru}}}, \tag{B.15}
\]

Here the derivatives are evaluated at \( \hat{y}_{\text{fid}} \equiv \hat{y}(\hat{d}_{\text{fid}}, \theta_{\text{tru}}) \).
Multipole moment ($l$)

$S^\ell (k_0) / 10^{-2} k^{-2}$

$\lambda = 400$

$\lambda = 20000$

Figure 15. Left: TT sensitivity kernels $S^\ell (k_0)$ for the Planck, WMAP-9 polarisation, ACT and SPT data (combination II) with $\lambda = 400$. The kernels are shown for $k_0 = 10^{-4}, 5 \times 10^{-4}, 10^{-3}, 2.5 \times 10^{-3}, 5 \times 10^{-3}, 7.5 \times 10^{-3}, 0.01, 0.015, 0.02, 0.03, 0.04, 0.05, 0.06, 0.075, 0.085, 0.105, 0.115, 0.125, 0.138, 0.15, 0.162, 0.18, 0.2, 0.3$ Mpc$^{-1}$. Note that the horizontal axis changes from a logarithmic to a linear scale at $\ell = 50$. Right: same as left panel but for $\lambda = 20000$.

Since the CMB data points depend on the underlying TT spectrum $s^{\ell \ell}_{TT}$ we introduce the TT sensitivity kernels

$$S^\ell (k_0) = \sum_i \frac{\partial Y_i}{\partial s^\ell_{TT}} \phi_i (k_0) = \sum_{Z, a, i} M^{(Z)}_{ia} \frac{\partial d^\ell_Z}{\partial s^\ell_{TT}} \phi_i (k_0).$$

The TT sensitivity kernels for some selected $k_0$ values are shown in figure 15. To a first approximation the amplitude of the sensitivity kernels varies inversely with the height of the TT spectrum because the PPS is almost scale-invariant. Thus the $k_0 = 0.015$ Mpc$^{-1}$ kernel, which corresponds to the first acoustic peak, is the smallest. The kernels are particularly well localised for the scales $0.01 \leq k_0 \leq 0.115$ Mpc$^{-1}$, below which the signal-to-noise ratio of the Planck data falls sharply. The ACT and SPT bandpowers, which sample the TT spectrum less densely, lead to more irregular sensitivity kernels. The kernels associated with the CMB acoustic peaks are narrower than those at the troughs. For $\lambda = 20000$ the kernels are broader and less localised than for $\lambda = 400$.

The functions

$$R (k_0, k) = \sum_{i, j} R_{ij} \phi_i (k_0) \phi_j (k),$$

$$Y (k_0, k_1, k_2) = \sum_{i, j, k} Y_{ijk} \phi_i (k_0) \phi_j (k_1) \phi_k (k_2),$$

known as resolution kernels are more suitable for plotting than the resolution matrices. The first-order kernel $R (k_0, k)$ describes the extent to which the estimated PPS is a smoothed version of the true PPS. For fixed $k_0$ it is a sharply peaked function of $k$ (ideally centred at $k = k_0$) which represents the wavenumber range over which the true PPS is smoothed.

Features in the true PPS $P_\zeta (k)$ much broader than the resolution kernel $R (k_0, k)$ are recovered well by the estimated PPS $\hat{P}_\zeta (k_0)$, while features much narrower are smoothed out. The resolution kernels for some chosen values of the target wavenumber $k_0$ are displayed in figure 16. Since the resolution kernels depend on both the integral kernels $\mathcal{K}^{(Z)}_a$ and the
error in the data, the greatest resolution is attained on intermediate scales where the cosmic variance and noise in the data is minimised. A clear pattern is that the resolution is better at wavenumbers corresponding to the 7 peaks of the CMB TT spectrum observed by Planck than the troughs. This is because the TT integral kernels are narrower at the acoustic peaks than the troughs. There is a loss of resolution at \( k \simeq 0.4 \text{ Mpc}^{-1} \) between the lower wavenumbers covered by the CMB and WiggleZ datasets and the higher wavenumbers covered by the VHS Lyman-\( \alpha \) data. Although this gap is spanned by the CFHTLenS weak lensing data it has comparatively poor resolution as it is sparser and noisier than the other datasets.

To measure the resolution we use the width of the resolution kernels, taken to be the quantity \( \ln \left( \frac{k_{75}}{k_{25}} \right) \), the logarithmic wavenumber interval between the 25th and 75th percentiles of the area underneath the absolute value of the resolution kernel. In figure 17 the kernel width is plotted against the location of the kernel, defined as the wavenumber of the 50th percentile \( k_{50} \). The greater resolution at the acoustic peaks and the increase in resolution caused by the addition of extra datasets can clearly be seen.
Figure 17. Left: resolution kernel width plotted against the kernel location with $\lambda = 400$ for the four data set combinations. Right: resolution kernel width plotted against the kernel location with $\lambda = 20000$ for the four data set combinations. The influence of the CMB acoustic peaks on the resolution is clearly apparent.

Using eq. (B.5) the total frequentist covariance matrix $\Sigma$ of the estimated PPS is

$$\Sigma \equiv \langle (\hat{y} - \langle \hat{y} \rangle) (\hat{y} - \langle \hat{y} \rangle)^T \rangle = \Sigma_F + \Sigma_P + \ldots,$$

(B.19)

$$\Sigma_F[i,j] \equiv \sum_{Z,a,b} M_{ia}^{(Z)} N_{ab}^{(Z)} M_{jb}^{(Z)},$$

(B.20)

$$\Sigma_P[i,j] \equiv M_{ia} U_{\alpha\beta} M_{jb},$$

(B.21)

where the angled brackets denote the average over an ensemble of spectra estimated from repeated identical independent measurements of the data and the background parameters. Thus to first order $\Sigma$ is the sum of $\Sigma_F$ which arises from the data noise and $\Sigma_P$ which arises from errors in the background parameters.

Tikhonov regularisation has a natural Bayesian interpretation as a two-stage hierarchical Bayes model with a hyperparameter $\tilde{\lambda}$, as discussed in [2]. The maximum a posteriori estimate that maximises the posterior distribution of the PPS given the data $P(\mathbf{y}|\mathbf{d})$ coincides with $\hat{y}$ when the prior distributions of $\tilde{\lambda}$ and $\theta$ are $P(\tilde{\lambda}) = \delta(\tilde{\lambda} - \lambda)$ and $P(\theta) = \delta(\theta - \hat{\theta})$. The Bayesian covariance matrix $\Pi$ which describes the shape of $P(\mathbf{y}|\mathbf{d})$ is then given by

$$\Pi^{-1}_{ij} = \frac{1}{2} \frac{\partial^2 Q(\mathbf{y}, \mathbf{d}, \hat{\theta}, \lambda)}{\partial y_i \partial y_j} \bigg|_{\hat{y}}.$$

(B.22)

As the regularisation parameter $\lambda$ decreases, each element of the recovered PPS is effectively dependent on fewer data points. Mathematically, each row of the sensitivity matrices $M_{ia}^{(Z)}$ becomes a narrower and more sharply peaked function of the index $a$. This means that the resolution kernels also become narrower, but the noise artifact term $\sum_{Z,a} M_{ia}^{(Z)} n_a^{(Z)}$ in eq. (B.5) becomes more significant as the noise vectors $n_a^{(Z)}$ are less averaged out. Thus there is an unavoidable trade-off between the resolution and the variance of the recovered PPS.

This can be seen in figure 18 in which two measures of resolution quality (kernel width and offset) are plotted against the reconstruction error. The error is computed from the frequentist covariance matrix $\Sigma_F$ averaged over $5 \times 10^{-3} \leq k \leq 0.25 \text{ Mpc}^{-1}$. The kernel
width is defined as in figure 17, but now averaged over the kernels $R(k_0, k)$ with $5 \times 10^{-3} \leq k_0 \leq 0.25$ Mpc$^{-1}$. The offset of the kernel $R(k_0, k)$ is defined as the quantity $|k_0 - k_0|/k_0$. The offset is averaged over the kernels $R(k_0, k)$ with $3.5 \times 10^{-4} \leq k_0 \leq 1.9$ Mpc$^{-1}$.

The trade-off curves in figure 18 are shaped like the letter L. The corner of the curves represents the optimum compromise between resolution and variance. The regularisation parameter values $\lambda = 400$ and $\lambda = 20000$ used in our analysis are close to the corner of the curves and are thus satisfactory according to this criterion.
