ABSTRACT

We study the stellar mass distribution for galaxies in 160 X-ray detected groups of $10^{13} < \text{Log}(M_{\odot}) < 2 \times 10^{14}$ and compare it with that of galaxies in the field, to investigate the action of environment on the build up of the stellar mass. We highlight differences in the build up of the passive population in the field, which imprint features in the distribution of stellar mass of passive galaxies at Log(M/M$_{\odot}) < 10.5$. The gradual diminishing of the effect when moving to groups of increasing total masses indicates that the growing influence of the environment in bound structures is responsible for the build up of a quenched component at Log(M/M$_{\odot}) < 10.5$. Differently, the stellar mass distribution of star forming galaxies is similar in shape in all the environments, and can be described by a single Schechter function both in groups and in the field. Little evolution is seen up to redshift 1. Nevertheless at $z=0.2–0.4$ groups with $M_{200} < 6 \times 10^{13} M_{\odot}$ (low mass groups) tend to have a characteristic mass for star forming galaxies which is 50\% higher than in higher mass groups; we interpret it as a reduced action of environmental processes in such systems.

Furthermore we analyse the distribution of sSFR–Log(M) in groups and in the field, and find that groups show on average a lower sSFR (by $\sim 0.2$ dex) at $z<0.8$. Accordingly, we find that the fraction of star forming galaxies is increasing with redshift in all environments, but at a faster pace in the denser ones.

Finally our analysis highlights that low mass groups have a higher fraction (by 50\%) of the stellar mass locked in star forming galaxies than higher mass systems (i.e. 2/3 of their stellar mass).

Key words. galaxy groups – galaxy evolution

1. Introduction

The galaxy stellar mass function (GSMF) is a very important diagnostic to perform a census of galaxy properties, and provides powerful means of comparison between the populations of galaxies in different environments.

Historically, the luminosity function has been the first diagnostic used to study the distribution of galaxy properties, since a magnitude is a more direct observable than mass (Schechter 1976; Binggeli et al. 1988). However, the development of stellar population synthesis models and deep multi–wavelength surveys have greatly improved our ability to estimate the stellar mass content in galaxies. We can now study the distribution of stellar mass, a parameter which is more directly linked to the total mass of a galaxy.

The galaxy stellar mass function is important for both cosmology and galaxy evolution to better understand the connection between galaxy and dark matter distributions, and their link to the environment. In particular, the shape of the GSMF and its evolution give very important insights into the processes that contribute to the growth in stellar mass of galaxies with time and that drive the formation and evolution of galaxies in different environments.

The GSMF has been extensively studied in deep fields, for galaxies of different colors and morphological types (Bundy et al. 2008; Baldry et al. 2004; Pozzetti et al. 2010) and in different environments (Balogh et al. 2001; Yang et al. 2009; Vulcani et al. 2010). Its shape has been described by a Schechter function (Schechter 1976), that is an empirical model also used to describe the luminosity function. When fitted to the data, the shape of this function changes both as a function of the galaxy type (star–forming/passive, or morphological type) and of the environment (Balogh et al. 2001; Bolzonella et al. 2010; Yang et al. 2009).

The low-mass end of the galaxy stellar mass function is an important constrain for galaxy formation models, which generally overpredict the observed number of dwarf galaxies (Weinmann et al. 2011). The availability of deeper optical and infrared data enabled a study of the low mass end of the GSMF, showing a more complicated behaviour than a single Schechter function. This result was already suggested by luminosity function studies, where an excess of faint galaxies has been revealed both in deep fields (Baldry et al. 2004; Trentham & Tully 2002; Blanton et al. 2005) and in studies focused on galaxy clusters.
and groups [Wilson et al. 1997; Hilton et al. 2005; Popesso et al. 2005; González et al. 2006]. In the light of these results, different authors suggested that the GSMF may be better described by a multicomponent model, such as a double power law (Yang et al. 2009), or a double Schechter function obtained by adding a second Schechter function, with a steep negative slope and a lower characteristic mass (Driver et al. 1994; Baldry et al. 2008; Drory et al. 2009). Thereby the first term, \( \phi_1(M) \), is identified with a population of massive galaxies and the second term, \( \phi_2(M) \), with a population of low mass galaxies.

From a theoretical point of view, the shape of the Schechter function (characterized by a slope and a characteristic mass) calls for a physical interpretation. On one hand, a mass function with a steep rising slope at low stellar masses is a generic prediction of CDM models (White & Reid 1978). If galaxies follow the underlying halos and sub-halos mass distribution, differences between the shape of the galaxies and dark matter mass distribution are likely driven by non-gravitational processes connected with star–formation and feedback in galaxies; therefore the slope of the GSMF is an important constraint for the modelling of non-gravitational processes. On the other hand, the characteristic mass which defines the knee of the GSMF \( (M^*) \) is interpreted as a threshold where galaxy growth by star formation is not an efficient process, and is overruled by growth through merging processes (Khochar & Silk 2009). Moreover, simulations have shown that the steep cut-off at high stellar masses can be reproduced by taking into account feedback from supermassive black holes as a main ingredients in galaxy evolution (Croton et al. 2006).

With the advent of large multi-wavelength surveys, data achieved a sufficient enough accuracy to provide a guideline for galaxy evolution models. Peng et al. (2010) demonstrated the fruitfulness of a data–based approach: starting from observed properties of the galaxy distribution in SDSS DR7 and zCOSMOS, these authors devise a simple description of how star formation is quenched in the global galaxy population. When this model is applied to a simulated sample of galaxies, it correctly reproduces the observed GSMF in the global field.

Since a large fraction of the universal stellar mass is formed in groups \( (<10^{11} M_\odot) \) (Crain et al. 2009), it is crucial to study the GSMF in these environments to have a complete understanding of the mass assembly. Another intriguing aspect of studying galaxy groups is the compelling evidence that most of the pre-processing of galaxies occurs in groups’–sized halos (van den Bosch et al. 2008; Wetzel et al. 2011) before falling in more massive structures. Furthermore, groups of galaxies exhibit a correlation between the baryon fraction locked in stars and the group mass (Giodini et al. 2009; McGaugh et al. 2010), suggesting that low mass systems are the most effective environment for the conversion of baryons into stars. Our aim is to use the GSMF as a tool to shed light on this phenomenon and constrain the stellar mass content of these systems.

Deep X–ray surveys, as the one performed on COSMOS (Scoville et al. 2007; Haslinger et al. 2007), provide for the first time enough information to perform a statistical study on a large sample of X–ray selected galaxy groups. We investigate the GSMF of the X–ray selected groups in the COSMOS 2 degs$^2$ field and compare it to that of clusters and the field. The COSMOS survey provides a unique database of photometric and spectroscopic data, together with deep X–ray data from XMM and Chandra, and the largest catalog of X–ray detected groups up to now. We take advantage of the X–ray data to provide a definition of environments based on the depth of the dark matter potential well, dividing between low mass and high mass groups. Furthermore, X-ray information provides evidence for a gravitationally bound nature of the identified groups and a better total mass proxy, giving a more solid basis for subsequent conclusions.

This paper is structured as follows: in section 2 we describe the sample of X–ray detected groups (2.1) and the sample of group member galaxies (in 2.2). In section 3 we present and analyze the GSMF for the COSMOS X–ray selected galaxy groups, comparing it with that of the field; in section 4 we study the fraction of baryons in galaxies in high and low mass groups and in section 5 we compare the stellar mass fractions obtained in this work with other values in the literature. Finally in section 6 we study the distribution of specific star formation rate in the different environments. Results are discussed in section 7.

We adopt a ΛCDM cosmological model \( (\Omega_m = 0.27, \Omega_\Lambda = 0.73) \) with \( H_0 = 71 \text{ km s}^{-1} \text{ Mpc}^{-1} \).

2. The sample

2.1. Galaxy groups in the COSMOS survey

The COSMOS field provides the largest catalog of X–ray selected groups obtained in a contiguous fields up to now. The catalog of COSMOS X–ray selected groups (status July 2010) contains 276 extended sources detected from a wavelet scale-wise reconstruction. The detection is performed on the co-added XMM-Newton and Chandra images, where point like sources have been subtracted from each dataset (Finoguenov et al. 2009; Leauthaud et al. 2010), and setting 4\( r \) as a threshold for the source detection. A detailed description of the extraction of X–ray characteristics is given in Finoguenov et al. (2007). The wealth of information available in the COSMOS database enables the optical identification of the groups both using photometric and spectroscopic data. Each group has been identified using a refined red-sequence technique as detailed in Finoguenov et al. (2010). Furthermore, spectroscopic identification of groups has been achieved through the zCOSMOS-BRIGHT program (Lilly et al. 2009), targeted follow-up using IMACS/Magellan (Finoguenov et al. 2007) and FORS2/VLT (Finoguenov et al. in prep.), as well as through secondary targets on Keck by the COSMOS collaboration. Following identification, the redshift of the individual groups is assigned on the basis of the available spectroscopy, or from the average photometric redshift of the red-sequence galaxies when less than two spectroscopic redshifts are available. The center of a galaxy group corresponds to the emission peak of the associated X-ray source. This X-ray center can be difficult to identify when the associated source is at the X-ray detection limit or a system is visually classified as a merger. In both cases a new center is assigned, which corresponds to the position of the most massive galaxy located near the X-ray center. A statistical treatment of the uncertainty in selecting the groups’ center can be found in George et al. (2011). The robustness of the centring is evaluated through visual inspection and is expressed by a quality flag for each entry of the COSMOS X–ray group catalog. For the present analysis we have excluded groups having an uncertain optical counterpart or multiple ones (i.e. with a flag > 3).

The X–ray detected groups span a large range of X–ray luminosities \( (5 \times 10^{40} \text{--} 3 \times 10^{43} \text{ erg/s}) \) and redshifts (0.08–1.9). We limit the sample to 0.2<\( z <1.0 \), to ensure high quality photometric redshifts (Ilbert et al. 2009) and a sufficient volume sampling. Also, we discard X–ray groups that fall outside the SUBARU area, and therefore have incomplete photometry (marked in red
Table 1: Characteristic of the Subsamples of COSMOS Groups

| Redshift | LOW MASS | | HIGH MASS |
|----------|---------| |----------|
|          | N       | Log(M_{200})^{a} [M_{\odot}] | N       | Log(M_{200})^{a} [M_{\odot}] |
| 0.2<z<0.4 | 51  | 2.1\times10^{14} | 8 | 8.2\times10^{14} |
| 0.4<z<0.6 | 20  | 3.5\times10^{14} | 3 | - |
| 0.6<z<0.8 | 35  | 3.5\times10^{14} | 3 | - |
| 0.8<z<1.0 | 17  | 4.2\times10^{14} | 24 | 6.7\times10^{14} |

Notes. (a) Median mass of the subsample.

in Figure 1. After this selection we obtain a sample of 160 X–ray groups out of which 132 (82% of the sample) have at least three spectroscopic members within R_{200} while 145 have at least two (90%).

The total masses of the X-ray groups are derived from the empirical L_{X}–M_{200}^{1} relation determined in [Leauthaud et al. 2010] via weak lensing analysis. The resulting sample of X–ray detected groups ranges between 1\times10^{13} and 2\times10^{14} M_{\odot} in total mass with a median of 3.5\times10^{13} M_{\odot}.

We divide the group sample into 4 redshift bins between z=0.2–1.0, spanning 0.2 in redshift each (0.2–0.4, 0.4–0.6, 0.6–0.8, 0.8–1.0), to study the behaviour of the galaxy stellar mass function as a function of the redshift for the group sample and the division in subsamples.

Moreover due to the very low number of high mass systems in the redshift bins 0.4–0.6 and 0.6–0.8 (1 and 2, respectively), we choose not to perform the analysis at these redshifts.

To study the behaviour of the galaxy stellar mass function as a function of the group mass, we divide the groups in two bins of M_{200}. We choose 6\times10^{13} M_{\odot} as the threshold between low mass and high mass systems. This choice allows to maintain a similar median mass in the two mass bins and across the redshift range, maximizing the number of systems used. In this way, even if our sample is not mass complete for the lower mass groups, we can compare samples with on average similar properties at different redshifts.

It is worth stressing that both the stellar mass for individual galaxies and the initial mass function (IMF) used in this paper are different than those used in [Giodini et al. 2009], where masses where computed from K-band photometry and the assumed IMF was that from [Salpeter 1955]. Differences between SED and K-band stellar masses are discussed in [Ilbert et al. 2010], while changing between a Salpeter and a Chabrier IMF reduces the stellar masses of \sim 0.25 dex. Since we select a magnitude limited sample, we can ensure to observe all galaxies above a mass threshold (completeness stellar mass), which is redshift dependent. To estimate the completeness mass we consider the galaxies in the faintest 20% of our sample and derive the stellar mass (M_{lim}) they would have if their apparent magnitude was equal to the sample limiting magnitude (i.e. i_{AB}=25). Then we define as completeness mass the value of the 95% percentile of the distribution in M_{lim} (the same method is applied in [Pozzetti et al. 2010]).

2 The quoted error is the median of the errors on the individual stellar masses. Those are statistical errors computed once the model that best describes the galaxy SED is fixed. Larger systematics effects may be present when comparing mass estimated with a different set of models [Longhetti & Saracco 2009].
of each of the redshift bins in which the groups’ sample is divided, separately for star forming and passive galaxies (passive galaxies have a slightly higher completeness mass than star forming galaxies). The ensuing values represent the stellar mass completeness as a function of redshift for our sample (Table 2). It is known that the distribution of galaxy properties is generally bimodal, being different for star-forming and passive galaxies (Strateva et al. 2001). When studying galaxy evolution it is therefore very important to separate the two populations: for this purpose we use the spectroscopic types attributed to individual galaxies as a by-product of the photo-z determination, on the basis of their best-fit broad-band spectral energy distributions (SEDs). In particular, passive galaxies in the photometric catalog these galaxies have an SED type consistent with an E (Polletta et al. 2007). These SED types represent a passive galaxies population in NUV–R at the lowest redshift bin is is the volume sampled by X–ray selected versus stellar mass. Red and blue symbols mark the classification as passive and star forming galaxies according to the spectrophotometric flag in the photometric catalog. Passive galaxies overlap with the associated sequence of red galaxies identified in rest frame NUV–R>3.5 and marked by the vertical line (Ilbert et al. 2009). The solid horizontal line marks the completeness stellar mass for passive galaxies at each redshift.

| Redshift | Log(M_{comp,passive}) [M_{\odot}] | Log(M_{comp,src}) [M_{\odot}] |
|----------|----------------------------------|---------------------------------|
| 0.2<z<0.4 | 8.6                              | 8.4                             |
| 0.4<z<0.6 | 9.1                              | 8.9                             |
| 0.6<z<0.8 | 9.6                              | 9.3                             |
| 0.8<z<1.0 | 9.9                              | 9.8                             |

Table 2: Completeness Galaxy Stellar Mass.

Fig. 2: NUV–R rest frame color (dust corrected) of galaxies within X–ray selected groups versus stellar mass. Red and blue symbols mark the classification as passive and star forming galaxies according to the spectrophotometric flag in the photometric catalog. Passive galaxies overlap with the associated sequence of red galaxies identified in rest frame NUV–R>3.5 and marked by the vertical line (Ilbert et al. 2009). The solid horizontal line marks the completeness stellar mass for passive galaxies at each redshift.

2.3. Galaxy stellar mass function of COSMOS groups

The distribution of galaxy stellar mass is obtained as follows. For each bin of redshift and total mass the observed background subtracted mass distribution for the COSMOS X–ray selected groups can be expressed as:

$$\phi(M) = \frac{1}{V_c} \left[ \sum_i N(M_i) - N_b(M) \right]$$

(1)

where N indicates the member galaxies, N_b is the contribution to the observed counts due to field galaxies, V_c is the volume sampled by X–ray groups and n is the number of systems in each bin of redshift and total mass. The volume sampled by X–ray groups is computed as a sum of comoving spherical volumes with radius equal to R_{200}.

N(M) is obtained by direct counting of the member galaxies above the completeness stellar mass in bins of 0.25 dex in stellar mass. In order to obtain the composite stellar mass distribution in the group galaxies we statistically correct each stellar mass bin for the contribution of background galaxies by subtracting the background galaxy distribution. The background distribution, N_b(M), consist of all the galaxies in the same redshift bin as the groups which are lying outside R_{200} of any groups (here–after called “field galaxies”). This distribution is renormalized by a factor V_{out}/V_{cylinder} with V_{out} being the volume outside group’s R_{200} and V_{cylinder} the volume where member galaxies are counted (see previous Section). We compute the background distribution from the whole survey field so that it is less affected by local fluctuations in the number density due to the large scale structure surrounding groups. However, works on the luminosity function based on SDSS data show that there is little difference between using a local and global background subtraction (Goto et al. 2003; Popesso et al. 2005).

It is worth noticing that our definition of field galaxies include those that do not reside in X-ray selected groups in our sample, but are not isolated and part of non-detected systems. In order to estimate possible contamination from surrounding large scale structure we repeat our analysis removing from the field galaxies’ sample those within 1-4x R_{200} of each groups (which mean considering only galaxies outside the turnaround radius of massive halos), and we do not find significant differences in the ensuing results.

The total uncertainties on $\phi(M)$ consist of the uncertainties on the stellar mass measurement and Poissonian errors. The former are estimated via a Montecarlo simulation that redistributes the
galaxies according to their 1σ confidence interval on the stellar mass estimate (as given in the photometric catalog). The Poissonian uncertainty is the 1σ variance for the low count regime computed as in Gehrels (1986).

To test our determination of the GSMF in the groups and in the field, we compare it with other results at low redshift: in Figure 3 we show the GSMF of all galaxies in low mass groups compared to those determined by Balogh et al. (2001) and Yang et al. (2009) using 2MASS and SDSS data respectively. The COSMOS field GSMF is compared with that of Baldry et al. (2008).

The GSMF we obtain for the field compares remarkably well with the independent determination by Baldry et al. (2008; red dashed line) on a spectroscopic sample, indicating that systematics on the stellar mass determination are under control, at least for the global distribution. The comparison with the groups’ stellar mass distribution found by Yang et al. (2009) is very encouraging, since the good agreement indicates that our group selection does not bias the galaxy distribution when compared to optically detected groups. We also find good agreement with the stellar mass distribution obtained by converting the K-band luminosity function found by Balogh et al. (2001). This suggests that our results can be easily compared also with those obtained in surveys where stellar masses for individual galaxies are not available.

Once tested that the global stellar mass distributions are robust when compared with previous studies, we proceed dividing the galaxy population between star forming and passive objects. In Figure 4 we show the composite, background subtracted stellar mass distributions of star-forming and passive galaxies in the COSMOS X–ray selected groups. The contribution of low and high mass groups is considered separately. Given the small number of systems, the stellar mass distribution of high mass groups at redshifts 0.4–0.6 and 0.6–0.8 cannot be robustly determined and is not used for the analysis.

We also show as a comparison the distribution of galaxy stellar mass in the field, defined as all coeval galaxies outside bound X–ray emitting structures. To enable the comparison in Figure 4 we normalize the distributions to their respective overdensity δ (over the critical one) at the redshift considered. The values of δ used are 200 for the groups and 1 for the field. In Appendix A we list the galaxy stellar mass distributions for low and high mass groups in COSMOS at different redshifts.

3. Parametrization of the composite GSMF

3.1. Star Forming Galaxies

The binned distribution of stellar mass for star forming galaxies can be described by a Schechter function with slope α and characteristic mass $M^\star$:

$$\phi_s(\log(M)) = \phi_s^\prime \left( \frac{\log(M)}{\log(M^\star)} \right)^{\alpha+1} e^{-\frac{\log(M)}{\log(M^\star)}}$$

where $M$ is the stellar mass.

We perform Montecarlo simulations of the galaxy distribution to quantify the effect of uncertainties on the shape of the observed galaxy stellar mass function. The observed distribution is modified by the effect of uncertainties on the stellar mass, that convolves the true mass distribution with the stellar mass error distribution. We can take this effect into account by modelling the stellar mass error distribution. The distribution of stellar mass uncertainties can be described at the first order as a Gaussian in log-space with rms $\sigma_{\log(M)}$ equal to 0.12 dex, which is the typical error on the stellar mass measurement (see Section 2.2). Montecarlo simulations of the galaxy distribution confirmed that the true distribution is correctly recovered by using a single gaussian convolution, even if the error distribution may be more complicated.

Therefore the observed galaxy stellar mass function is then given by:

$$\phi(\log(M)) = \frac{1}{\sqrt{2\pi}\sigma_{\log(M)}} \int \phi_s e^{-\frac{(\log(M)^\prime-\log(M))^2}{2\sigma_{\log(M)}^2}} d\log(M)$$

In galaxy groups the observed stellar mass distributions are the sum of the background and the true Schechter function convolved with the distribution of uncertainties. By fitting this convolved function to the observations, the Schechter function $\phi_s$ thus determined describes the “true” mass function which would be measured in absence of uncertainties on the stellar mass. Due to the low number of counts in some stellar mass bins (at high stellar mass), $\chi^2$ minimization is not an appropriate technique and therefore we use a maximum likelihood fitting method. We maximize the logarithmic likelihood ($\log(\ell)$) that the model may describe our data with respect to the Schechter parameters; 1σ confidence levels on the best fitting parameters are obtained by identifying the interval at which $-2\log(\ell)$ is lower by 1 than at its maximum. We verified through Montecarlo simulations that our method could recover the correct Schechter function, as well as the size of the parameter uncertainties.

The Schechter parameters obtained for the most likely function are listed in Table 3 together with the 1σ confidence intervals. In Figure 5 and 6 we show the best fit Schechter functions (in cyan) for star forming galaxies in low mass and high mass groups respectively, plotted over the observed background subtracted stellar mass distribution.

A visual inspection of Figure 4 (upper panel) suggests that the distributions at low stellar mass seem remarkably similar in groups and the field at all redshifts. We can confirm this in a quantitative way by comparing the values of $\alpha$ found in groups and the field. The slope is compatible with being the same in all
Fig. 4: Upper plot: Galaxy stellar mass distributions of star forming galaxies in the field (squares), low mass groups (black points) and high mass groups (magenta triangles). Different panels show different redshift bins. In each panel the vertical line marks the completeness stellar mass. The distributions are normalized to their respective overdensity $\delta$ (over the critical one) at the redshift considered. The values of $\delta$ used are 200 for the groups while we assume an overdensity of 1 for the field. Lower plot: Same as the upper panel but for passive galaxies.
environments and it does not show a significant evolution over the whole redshift range (but for the last redshift bin, where the derived slope may be artificially flat as discussed in the next section).

This similarity is not confirmed when looking at the high stellar mass part of the distribution. At low redshifts the characteristic mass of low mass and high mass groups is offset, with the one of low mass groups being higher. When considering the single-parameter uncertainties on $M^*$ (listed in Table 3), the discrepancy is not statistically significant ($\sim 1\sigma$). Nevertheless it is interesting to consider the effect of the correlation with the slope $\alpha$ as shown in Figure 7 where we draw the iso-likelihood contour for the combination of best fitting $\alpha$ and $M^*$, corresponding to 68.3, 95.4 and 99% confidence levels (corresponding to 1, 2, 2.5 sigma).

As can be seen from the plot, for any common value of $\alpha$ between the high and low mass groups contour region, the $M^*$ is different at more than 2$\sigma$. Therefore if $\alpha$ is the same in high and low mass groups, the significance of a discrepancy in the characteristic mass is enhanced, which suggest the bulk of star forming
galaxies being more massive in low mass groups. Furthermore, the values of characteristic mass we find for star forming galaxies in the field and in groups are consistent with those estimated in Bolzonella et al. (2010) for low density (D1) and high density (D4) environments, respectively. A hint of the offset we observe between $M^\star$ in differently dense environments could be seen also using the Bolzonella et al. (2010) values. However the large uncertainties on their estimates strongly affect any conclusion in this respect. We also note that the characteristic mass of star forming galaxies in all the environments is remarkably stable across the redshift range. This finding confirms and extend to the regime of groups that by Ilbert et al. (2010), who found the same redshift independence in the global galaxy stellar mass distribution.

On the other hand it is known that the fraction of star forming galaxies decreases with time in massive clusters (Butcher-Oemler effect; Butcher & Oemler 1978) and that denser environments are dominated by non star forming galaxies. At redshifts 0.2–0.4 low mass groups exhibit 50% more star forming galaxies than high mass groups. Interestingly at redshifts 0.2–0.4 (~0.4) is still within 1.5 $\sigma$ or the newly estimated one, while the same is not true at high redshift where the steep slope found at low redshift is rejected at more than 3 sigma significance. As a further test, we perform a fit of 50 Monte Carlo realizations of the observed GMSF of low mass groups at z=0.2–0.4, using $\log M_\star = 8.35$ and 10.0 $M_\odot$ as limiting masses. While the former leads to a slope steeper than -1.3 as best fit solution in the majority of the cases, the same happens only in 11 out of 50 cases when using the highest limiting mass. Furthermore the means of the two distributions of best fitting slopes with high and low limiting mass differ at ~2 sigma significance.

The previous test tells us that probably a single Schechter function is not the most adequate model to describe the stellar mass distribution of star forming galaxies, and that more information is contained in the low mass part of the distribution. However, it is possible to pinpoint the steep slope of the function only with deep data (e.g. log(M/M_\odot) >10.0), and this may explain why other works on galaxy groups performed with shallower data find flatter slopes than ours (e.g. Yang et al 2009). However, considering an intermediate environment in terms of star forming galaxy content, when compared to lower and higher mass systems, and it indicates an extension of the Butcher-Oemler effect to galaxy groups. It is also interesting to note that the differences among the various environments increase with time, indicating a faster evolution of the fraction of star forming galaxies in more massive groups.

3.2. Considerations

When fitting a Schechter function to the galaxy stellar mass distribution, we consider only the stellar mass bins not affected by incompleteness, in order to ensure a robust estimation of the parameters. If the model adequately represents the data, restricting the range where the fit is performed should not affect the final result (except for increasing the uncertainties on the parameters). However, when using at redshift 0.2–0.4 the same limit in stellar mass as at high redshift, the resulting best fit slope is flatter (near to -1.0) and the associated error increases by a factor of two. Therefore, the slope estimated in the previous section at z=0.2–0.4 (~1.4) is still within 1.5 $\sigma$ or the newly estimated one, while the same is not true at high redshift where the steep slope found at low redshift is rejected at more than 3 sigma significance. As a further test, we perform a fit of 50 Monte Carlo realizations of the observed GMSF of low mass groups at z=0.2–0.4, using $\log M_\star = 8.35$ and 10.0 $M_\odot$ as limiting masses. While the former leads to a slope steeper than -1.3 as best fit solution in the majority of the cases, the same happens only in 11 out of 50 cases when using the highest limiting mass. Furthermore the means of the two distributions of best fitting slopes with high and low limiting mass differ at ~2 sigma significance.
since the aim of this paper is a first characterization of the GSMF of galaxy groups to be compared with other observations and galaxy evolution models which adopt a single Schechter description, we also assume this prescription and leave a more detailed analysis of the shape of the low mass GSMF to a future work. The test above suggests that at high redshift, the slope may be artificially flat, due to the lack of deeper data. The data points below the completeness mass can potentially identify an artificially flat slope, as they represent lower limits. For high-mass groups at redshift 0.8-1.0, the first two points below the completeness mass are higher than the prediction from the best-fit model with a flat slope. We therefore re-fit the slope including these two data points, and find a steeper slope (~1.2) compatible within 1σ with that found at low redshift. In the following we use this result instead of the artificially flat fit above the completeness mass, noting that if we would have deeper data, the slope would even be somewhat steeper.

3.3. Passive Galaxies

As can be seen in Fig. 3, the observed stellar mass distribution of passive galaxies is characterized by a different shape than that of star forming galaxies in both subsamples of groups and the field. In groups the distributions flatten at low masses. Conversely, in the field the low mass distribution exhibits a “dip” around \( \log(M/M_\odot) \sim 9.5-10.0 \). This behaviour can be hardly described by a single Schechter function: previous works suggested that this more complicated shape is produced by two different populations of galaxies, each with a GSMF described by a single Schechter function. Following this prescription we parametrize the galaxy stellar mass function with a sum of two Schechter functions where \( \phi_2 \) accounts for the steep rising slope towards low masses (secondary component) and \( \phi_1 \) for the flatter slope at high masses (primary component).

If the galaxy stellar mass function stems from two classes of galaxies, it is reasonable to assume that at least one of them has something in common with the distribution of star forming galaxies, especially if the process that has quenched the star formation is fast enough to prevent their further growth in stellar mass via star formation.

It is also reasonable to assume that this would happen more likely for galaxies of low mass, that are more strongly affected by environmental effects. Therefore, assuming that low mass quenched galaxies stem directly from the distribution of star forming galaxies, we set the \( M^* \) of the low mass component (\( M^*_1 \)) to that found for star forming galaxies.

On the other hand, massive galaxies are generally segregated towards the center of the potential well of a group because of dynamical friction, where merging episodes are more likely to occur. This may produce some change in the characteristic mass of the primary component from that of star forming galaxies, therefore we leave this parameter as free.

It is also true that \( M^* \) for star forming galaxies is remarkably stable across the cosmic time. Thus we may assume that star formation and its shut off are acting at the same pace for massive galaxies following Peng et al. (2010). Translating this assumption into requirements on the fitting parameters, the \( \alpha_1 \) can be fixed to

\[
\alpha_1 = \alpha_{SFG} + (1 + \beta)
\]

where \( \beta \) is the slope of the specific star formation rate (sSFR)–stellar mass relation (Peng et al. 2010). In first approximation \( \beta \) can be set to zero, since the dependence of the sSFR on the stellar mass is found to be very weak (Elbaz et al. 2007, Noeske et al. 2007). However, given that at high redshift \( \alpha_{SFG} \) can be eventually affected by systematics discussed in Section 8, we also consider the case where the value of \( \alpha_1 \) is fixed to -0.4 at \( z > 0.4 \). Furthermore, since at redshift larger than 0.4 the high completeness mass prevents us from constraining the slope of the secondary component, we fixed it to that found at low redshift.

In Figures 9 and 10 we show the resulting best fit Schechter functions over–plotted to the background subtracted observed stellar mass distribution for low and high mass groups respectively.

In Table 4 we list the best fitting Schechter parameters. In some cases at high redshift we are unable to constrain the secondary component, and the formal best fit \( \phi_2 \) results in a negative value. In these cases we did not fit the second component and we set \( \phi_2 = 0 \).

We find evidence for a steeply rising slope at low stellar masses in the mass function of passive galaxies in the field. To ensure the robustness of the measure against a contamination from star forming galaxies, we repeat the slope estimation with the additional condition of SFR<\(10^{-2} \) M_\odot y^{-1} and NUV-R color larger than 3.5. The latter is the same condition applied in Ilbert et al. (2009) to select quiescent galaxies. In both cases the steepness of the slope is confirmed.

We also test against contamination from catastrophic errors in the photometric redshift determination of high redshift galaxies. Such galaxies, being faint, will be assigned a low mass and may contribute to the lower part of the galaxy stellar mass distribution. We scale the distribution in i magnitude of the galaxies with \( z > 1 \) by an upper limit of 20% catastrophic failures, as estimated by Ilbert et al. (2009) at \( i > 23 \), and we find that the contamination becomes important only at \( i > 26 \), well beyond our limiting magnitude. Therefore contamination from misidentified high redshift galaxies can be ruled out as an explanation for the steepness of the observed slope.

We also test against the contamination from the outskirts of the large scale structure by repeating the analysis with a more conservative selection of the background, removing galaxies within 3\( \times R_{500} \) from the center of a group. Also in this case the GSMF show a steep slope at low mass, confirming the robustness of our finding as a feature of the field. At low redshift, the secondary slope in the field appears to be significantly steeper than that found for star forming galaxies (~1.8 when compared to ~1.4, with a difference at the 7σ level). This indicates that the quenching of low mass galaxies may be more complicated than that predicted by simple models of galaxy evolution (Peng et al. 2010). Indeed, if the observed stellar mass distribution of star forming galaxies is the same as that of the progenitors of the quenched galaxies, our findings suggest that during the process of quenching this distribution is not conserved. Unfortunately we cannot well constrain the slope at higher redshift due to incompleteness, but we can fit the points also below the completeness threshold to obtain a lower limit to the slope. The estimated lower limits indicate that a rising slope at low stellar masses exists at least since redshift 0.6. We do not draw any conclusion on the highest redshift bin since the points at \( \log(M_{stellar} < 10 \) are likely affected by strong incompleteness. Indeed we observe a strong evolution in the fraction of passive galaxies with stellar mass \( \log(M_{stellar} < 10 \) at these redshifts (see Figure 2) which is not found in studies on the global population of galaxies (Bundy et al. 2006 e.g.).

Interestingly, such a steep slope is not found in groups, where
After integrating the GSMFs down to $10^9 \, M_\odot$, to obtain an estimate of the total stellar mass in passive and star forming galaxies in different environments. We compare this quantity with the total amount of baryons available, estimated as $M_{200} \times f_b$, where $f_b$ is the baryonic fraction from WMAP7 (Dunkley et al. 2008). The resulting quantity represents the fraction of baryons in galaxies, which is an indication on how efficiently the conversion of baryons into stars acts as a function of redshift and total halo mass (similarly as in Mandelbaum et al. 2006). Figure 11 reveals many interesting trends in the relation between baryon conversion efficiency and galaxy properties. We find that star forming galaxies in low mass groups have the highest conversion efficiency: when compared to passive galaxies in the same environments the difference amounts to at least a factor of two at all redshifts. Interestingly, independent measures of the baryonic conversion efficiency through galaxy-galaxy lensing find a similar result (Mandelbaum et al. 2006). We also note that star forming galaxies in high mass groups show a much lower contribution to the baryon fraction than the low mass ones, at low redshift. Indeed the fraction of baryons in star forming galaxies in high mass groups is roughly a factor of 1.5 lower than in low mass groups: although the significance of this result is less than a two sigma, it is suggested that in more massive halos the fraction of baryons locked up in star forming galaxies is lower. A similar result is found in RCS2 using galaxy-galaxy lensing (van Uitert et al. 2011).

Conversely the amount of baryons in passive galaxies, appears to be similar in low mass and high mass groups, being already set at redshift 0.8–1.0. The difference between the fraction of baryons in star forming and passive galaxies holds (if not increased) also at higher redshift, being set already at redshift 0.8. On the other hand the difference in the contribution of star forming galaxies to the baryonic fraction seems to be smaller at high redshifts, where the two values are more similar due to an increased amount of baryons locked in star forming galaxies in high redshift massive groups.
Fig. 9: Upper Panel: Schechter function fit to the GSMF for passive galaxies in the field. The dashed line marks the convolved Schechter function, the solid one the “true” Schechter function. The magenta and blue lines represents the two components of the double Schechter function (in red). The solid vertical line marks the completeness stellar mass. Lower Panel: the same as for the upper panel but for low mass groups.
showed as black points in Figure 12. As a consistency check we compare our average stellar mass fraction with those published in Giodini et al. (2009) for low mass groups. We correct these values for a Chabrier IMF and for the additional systematic shift by ~0.2-0.4 dex between K-band and SED computed stellar masses discussed in Ilbert et al. (2010) (we use 0.3 dex as an average value).

We also compare our results with the recently published average groups’ stellar mass fractions by Leauthaud et al. (2011); these authors constrain the fraction of stars in group-sized haloes by using a statistical Halo Occupation Distribution model that jointly constrained by data from lensing, clustering, and the stellar mass function. In Figure 12 we show the comparison of the values of average stellar mass fraction computed from the composite GSMF for low mass groups ($M_{200} < 6 	imes 10^{13} M_\odot$) to that found in Giodini et al. (2009) and Leauthaud et al. (2011) for similar average total masses (we approximate the difference between $M_{200}$ and $M_{500}$ to 30%, which corresponds to the difference for NFW haloes with concentration equal 5).

Reassuringly, Figure 12 shows a broad agreement between the three measurements, even if computed with different methods, confirming the robustness of the estimated stellar mass fraction values. The significantly lower value of the average stellar mass fraction at $z \sim 0.4$ is not surprising since there is a lack of massive galaxies in COSMOS at this redshift. (see also Pannella et al. 2009).

6. The sSFR in galaxy groups

In order to better understand the differences in the galaxy stellar mass function between groups and the field, we analyse the distribution of the specific star formation rate (sSFR=SFR/M, where M is the stellar mass of a galaxy). The specific star formation rate is a side product of the SED fitting of the photometric points for each galaxy performed by Ilbert et al. (2009). In Figure 13 we show the sSFR as a function of the stellar mass for galaxies associated to groups (in red) and to the field (in yellow), while circles mark the median values of the distributions in stellar mass bins.

The distributions in the two environments cover approximately the same region in the plane; when plotting the median values in bins of mass the median sSFR in the field (empty circles) is higher than in groups (solid circles). However, even if the difference between the two median values is not significant at all
stellar masses, when comparing the individual values, it is significant that the values of median SSFR in groups are consistently lower than those in the field. The inset histograms in Figure 13 show the distribution of the difference in dex between these median values: at low redshift the typical discrepancy amounts to ~0.2 dex. This difference is not unexpected since it has already been shown that the median sSFR, at least in massive galaxies, declines as a function of local density (Kauffmann at al 2004; Patel et al. 2009). The difference we find is similar to that found using SFR measurement from MIPS sources in different environment (Patel et al. 2009; green points in Fig. 13).

Our finding suggests that the population of star forming galaxies is somehow modified in its capability of forming stars, by the presence of a surrounding environment. To strengthen this point we perform a KS test on the data—points to test if the sSFRs in groups and field are consistent with being drawn from the same distribution. We only consider points above the highest completeness mass. The associated probabilities are below 1% at all redshifts, suggesting that the two distributions are different at a high level of significance. Indeed if we compute the normalized cumulative sSFR distribution in the different environments and compare the median sSFR above the completeness mass, this value is lower for groups than field. This means that low mass groups show an excess of low-sSFR galaxies. These results suggest that the distribution of sSFR is strongly modified when a galaxy enters in a structure, in agreement with recent findings of a "reduced star-formation" galaxy population in groups and clusters (Vulcani et al. 2010; Balogh et al. 2010).

Having a large range of redshift for both field and groups environment, we can point out that the field distribution at redshifts 0.2–0.4 resembles that of groups at z=0.6–0.8 by matching the median of their cumulative sSFR distributions. If the difference in sSFR distribution corresponds an age difference, it suggests a delay by ~3 Gyr between field and groups. A similar delay between higher and lower density environments has been quoted by Bolzonella et al. (2010).

Finally Figure 13 shows the distribution of highly star forming (>1M⊙y⁻¹) galaxies in groups (red histogram) and the field (line-filled histogram). The two distributions do not exhibit significant differences at z=0.4, while at lower redshift we note that the galaxies with higher star formation rates (>30 M⊙y⁻¹) are completely absent in X-ray selected groups.

7. Discussion

The analysis of the galaxy stellar mass function revealed intriguing differences between groups and the field. Interpreting these differences can tell us how the build up of the stellar mass in galaxies (which is a local process) is affected by global properties of the parent halo. In the following sections we discuss our results.

7.1. Star Forming Galaxies

In our analysis we show that the stellar mass distribution of star forming galaxies can be described as a single Schechter function at all redshifts and in all the environments examined in this work (field, high and low mass groups). However, at z=0.2–0.4 low-mass groups exhibit a galaxy stellar mass distribution where the characteristic mass tends to be larger and the slope less negative than the corresponding parameters of the field GSMF. The tendency towards a 50% larger characteristic mass of the star forming galaxies in low-mass groups with respect to the field holds when the slope of the star forming GSMF is set to be equal to -1.4. The same is not seen in larger systems, where the fraction of red galaxies increases at a given mass: it is likely that such galaxies have been quenched more efficiently in massive groups, explaining the difference in characteristic stellar mass for star forming galaxies between these two environments.

A possible explanation for the presence of massive star forming galaxies in groups may be that the quenching is proceeding at a slower pace in groups than in massive clusters, enabling these systems to retain for a longer time the necessary fuel for star formation. Interaction with the surrounding hot gas in groups may lead to rejuvenation of the star formation (Gavazzi & Jaffe 1985). However, our analysis of the specific star formation rate distribution indicates that the median values are lower in these environments at least since redshift 0.8, suggesting that rejuvenation may be prevented in galaxy groups. This indication is supported by the presence of a large fraction of galaxies with intermediate color ("green valley" galaxies) and reduced star formation rates, in galaxy groups at z~0.8 (Balogh et al. 2010).

Therefore, if the same process is responsible for quenching star formation in groups and more massive structures, our findings suggest that this process is downsized or slowed down in galaxy groups. As a consequence, in the two-process scenario drawn by Peng et al. 2010, the "mass quenching", driven by feedback processes, may depend also on the environment.

Furthermore we find that the fraction of star forming galaxies is larger in the field than in groups, at any stellar mass. The ensuing suggestion that the field hosts a star formation activity which is more extended in time is supported by the larger values of sSFR obtained for field galaxies with respect to those in groups. This finding complements results obtained with smaller samples by Patel et al. (2009) and in more massive structures by Vulcani et al. (2010a). Interestingly the same is not found in similar analysis performed on optically detected groups (McGee et al. 2011), which may indicate that the quenching strength is larger in the evolved and virialized X-ray detected systems. If galaxy groups significantly contribute to globally reduce the star formation, environmental effects already effective on groups’ scale, such as strangulation, are important in shaping the distribution of galaxy properties in more massive structures. Furthermore our results agree with a scenario in which
environment regulates the time-scales of star formation history as suggested by observations of cluster and field galaxies at high redshift (Rettura et al. 2011).

Another interesting feature of the characteristic mass of star forming galaxies in groups is its remarkable stability between redshift 0.2 and 1.0. As already suggested by Peng et al. 2010, this fact can be understood if the mass quenching proceeds at the same pace as the star formation rate. Indeed if feedback processes are responsible for the quenching of star formation in massive galaxies, this dependence is expected (Kaviraj et al. 2007). As a consequence, if the star formation rate is decreased in groups, so is the mass quenching, supporting the interpretation for the presence of more massive star forming galaxies than in the field.

Furthermore, our findings confirm that galaxy evolution is faster in higher density environments, as indicated by the more rapid decline in the fraction of star forming galaxies in groups than in the field. By matching the cumulative distributions of sSFR in different environments, we estimated the delay between low mass groups and field being roughly 3 Gyr. This corresponds to a growth by $3\times10^9 M_\odot$ in stellar mass assuming the star formation rate of a typical galaxy as the Milky Way ($\sim 1 M_\odot$ y$^{-1}$). This amount is much lower than the difference in characteristic mass between groups and field, indicating that the field will never reach the mass distribution of groups, where the build up of mass has been more efficient. Consistently, only field galaxies exhibit values of the SFR that exceeds $30 M_\odot$ y$^{-1}$ at $z<0.4$. These results point towards a strong evolution of the SFR per unit of halo mass at $z<0.4$, in agreement with recent results from Herschel data (Popesso et al. 2010).

A synthetic view of the previously described behaviours is offered by the redshift dependence of the star forming galaxy fraction shown in Figure 8 for the three environments considered in this work: there are less and less star forming galaxies as the universe ages, but the denser the environment the lower this fraction. In other words, groups are intermediate environments when considering the Butcher-Oemler effect (Kauffmann 1995, Wilman et al. 2005, Gerke et al. 2007).
A word of caution should be spent when considering the evolution with redshift of the low mass systems examined in this paper. In fact, due to the bias towards brightest systems at higher redshifts introduced by the X-ray selection, the median mass of low mass groups at *z* = 0.8–1.0 is a factor of two higher than that at *z* = 0.2–0.4. Therefore in this work we do not aim at constraining the properties of the progenitors of redshift low mass groups, whereas at describing how groups with similar M<sub>200</sub> appear at different epochs. In general a higher median mass does not affect largely our results on SFR and baryonic fraction evolution, but turns our results in lower limits on the evolution. Indeed both these quantities decrease with increasing mass, diminishing the strength of the evolutionary trend. In order to confidently draw conclusions on the evolution of the GSMF a further work on a complementary sample of high redshift low mass groups from *Chandra Deep Field South* is ongoing (Giodini et al. in preparation).

Finally our analysis highlighted environmentally dependent differences in the amount of baryons locked in stars in different types of galaxies. Low mass groups show a higher fraction of star forming galaxies when compared to high mass groups and clusters. Translating this to the amount of baryons corresponding to star forming galaxies, 15% of the baryons are distributed in stars within star forming galaxies in low mass groups at *z* = 0.2–0.4, but only 10% in higher mass systems. Thus, in spite of the fractional increase of the number of passive systems at later epochs, about two thirds of the total stellar mass of a group (excluding the intra-cluster light) is locked in star forming galaxies at *z* = 0.3. Furthermore, the large amount of baryons in star forming galaxies in low mass groups is already settled at redshift 0.8 and it may be evolving towards a lower value at *z* = 0.8–1.0.

In Giodini et al. (2009) we found that the fraction of stars per unit halo mass (f<sub>star</sub>) is a function of M<sub>200</sub> for systems with 10<sup>13</sup> < M<sub>200</sub> < 10<sup>15</sup> M<sub>⊙</sub> at *z* = 1. Interestingly, the difference in f<sub>star</sub> between groups of M<sub>200</sub> corresponding to the median for low and high mass groups used in this work is comparable with that in the fraction of baryons locked in star forming galaxies. This suggests that a relative excess of baryons in star forming galaxies within low mass groups can explain the difference in f<sub>star</sub> in groups of different M<sub>200</sub>. At a first glance we could try to explain the higher fraction of baryons with a recent infall of star forming galaxies in low mass groups. If so we would expect that the total stellar mass in star forming galaxies does not depend on the total mass of the structure (i.e. on its volume), but on the collecting area. Assuming that the total stellar mass of passive galaxies is a good tracer of the total mass of the system, we expect that

\[
\frac{M_{\text{star}}}{M_{\text{baryons}}} \propto \frac{1}{R_{200}}
\]

However we find that the average growth of the amount of baryons locked in star forming galaxies as a function of M<sub>200</sub> is faster than that predicted using the median mass of our group subsamples (a factor of 2 against 1.5). This leads us to the conclusion that galaxy groups of ~3 × 10<sup>13</sup> M<sub>⊙</sub> may have a more efficient conversion of baryons into stars. A first tantalizing evidence of an enhanced baryonic conversion efficiency in galaxy groups was found by McGaugh et al. (2010). We confirm this result and in addition show that the excess baryons are locked in star-forming galaxies. It is worth noticing that the enhanced baryonic conversion efficiency in less massive galaxy systems likely has a higher metal enrichment as a consequence. Interestingly, this is found at the mass regime of clusters in the local Universe (Zhang et al. 2011).

### 7.2. Passive Galaxies

The analysis of the data presented in this paper show the existence of passively evolving galaxies with stellar masses larger than 10<sup>10</sup>M<sub>⊙</sub> up to redshift 1, whatever the surrounding environment (i.e. both in the field, high and low mass groups). This is a signature of an origin likely not connected with the large scale environment, but with processes internal to massive galaxies (the so called “feedback”). These passive galaxies dominate the whole population of galaxies with stellar mass larger than 10<sup>10</sup>M<sub>⊙</sub> at all redshifts in groups, while in the field they become dominant only at *z* < 0.6. On the other hand, the population of low mass passive galaxies (M < 10<sup>10</sup>M<sub>⊙</sub>) builds up since *z* = 1 in a continuous fashion, both in groups and in the field. Interestingly, the difference in the GSMF of passive galaxies between groups and field decreases by a factor of 2–3 from *z* = 0.8–1.0 to *z* = 0.2–0.4, indicating that field and groups were increasingly similar at higher redshift. At the same time, the number density of passively evolving galaxies with stellar masses in the range of 2 × 10<sup>9</sup>–2 × 10<sup>10</sup> M<sub>⊙</sub> is lower in the field than in groups. This difference increases when more massive groups are considered, which suggests the existence of a process of “secular quenching” that depends both on environment and stellar mass. Therefore, the GSMF of passive galaxies cannot be described by a single Schechter function whenever the data extend to Log(M/M<sub>⊙</sub>) < 10 (at *z* = 0.8). In this case a suitable fit is achieved by using a double Schechter function, where the second component is sensible to the behaviour of lower mass galaxies. When using this parametrization, we find the slope of the low mass component of the mass function for passive galaxies to be different between the groups and the field. This slope is quite steep (~1.8) in the field at odds with predictions based on SDSS and zCOSMOS data (Peng et al. 2010), according to which it should be as steep as that of star forming galaxies. The groups GSMF, instead, behaves as prescribed by the predictions, with a low mass slope that is compatible with that of star forming galaxies.

Interestingly, a hint for a rising slope at low mass can be seen in [Hibbert et al. (2010)](their Fig. 11), despite the higher cut in stellar mass due to the selection according to IRAC photometry. The latter authors divide their sample according to morphology: interestingly the rising slope disappears for quiescent galaxies with an elliptical morphology. Therefore the low mass upturn is likely to be associated with quenched galaxies which are not ellipticals. These galaxies are connected to environmental processes already active in groups such as gas stripping and starvation caused by a diffuse intra-group medium, or harassment. Indeed it is likely that the low mass component of the GSMF stems from quenching of satellite galaxies due to environmental effect (“environmental quenching”), while the high mass component is subject to events that shut off star formation via feedback processes (“mass–quenching”). The model of galaxy evolution suggested by (Peng et al. 2010) predict the low mass slope to be the same in all environments, since environmental quenching is assumed to be independent on the halo mass.

The presence of an upturn in our data is likely enhanced by the lack of intermediate mass galaxies in the field. This effect produces a “wiggle” in the GSMF between 10<sup>9</sup>–10<sup>10</sup> M<sub>⊙</sub>, which may be explained by a delayed appearance of passive galaxies of this mass in the field. A similar interpretation has been proposed by Tanaka et al. (2005) in a study on the build up of the faint end of the red sequence as a function of the environment.
They found that the ratio of giant (Log(M/M⊙) >10.6) to dwarf (9.7<Log(M/M⊙)<10.6) red sequence galaxies is larger in the field at any redshift, indicating that such faint galaxies are relative rare in the field.

Therefore our finding suggest that the build up of the the secondary quenched component is independent of the stellar mass in groups, as witnessed by the flatness of the slope of the GSMF, whereas in the field the quenching of low mass galaxies depends on their stellar mass. In particular the very steep slope found at Log(M/M⊙)<9.5 indicates a preferential quenching of such galaxies. Interestingly, semi–analytic models implementing the latest recipes of galaxy evolution fails to reproduce the fraction of dwarf passive satellites in structures, leading to an overproduction of low mass quenched galaxies (Weinmann et al.2011, e.g.). Current models struggle in justifying the destruction of these low mass galaxies via environmental processes, however the introduction of an environmental dependence in the quenching process, as suggested by our data, may alleviate this problem.

8. Conclusions

In this paper we investigate the distribution of stellar mass in galaxies within X-ray detected galaxy groups in the COSMOS survey.

After building the composite distributions for a sample of 160 groups divided into two sub-samples of high and low mass groups, we investigate the shape of the distribution for passive and star forming galaxies, comparing it to that of the field. Our analysis sheds light on how the transition between star-forming and passive galaxies occurs in different environments.

In particular, we highlight how the field build up at low redshift a population of low mass (M<10^9.5 M⊙) quenched galaxies which does not appear in groups and we unveil the slower build up of an intermediate mass (10^9.5 <M<10^{10.5} M⊙) quenched component in the field. As a consequence the distribution of stellar mass for passive galaxies shows differences in the shape between the groups and the field.

On the other hand, the stellar mass distribution of star forming galaxies is similar in the shape in all the environments and can be adequately described by a single Schechter function. However, we find indication for the bulk of the stellar mass in star forming galaxies being more massive in low mass groups then in high mass groups at low redshift (M200 ∼6×10^13), and we interpret this as the quenching process acting at a slower pace.

More generally we find that the distribution of sSFR is different between X-ray detected groups and the field, with groups showing median star formation rates lower than the field at all stellar masses, and we estimate the delay between field and structures to be ∼3 Gyr. Accordingly the fraction of star forming galaxies in groups is lower than in the field at all redshifts, with low mass groups being intermediate between field and more massive systems. In general the significance of the above findings decreases at high redshifts, suggesting that groups and field may be sharing more similar properties at z∼1.

Finally, we find that despite the increase of the passive population at lower redshift, at z=0.2-0.4 groups have two thirds of their stellar mass locked in star forming galaxies and low mass groups exhibit a larger fraction of baryons in star forming galaxies, in agreement with recent findings suggesting that that these systems convert more efficiently baryons into stars.
