ABSTRACT

An NIR (1.18–1.35 μm) high-resolution spectrum of the gravitationally lensed QSO APM 08279+5255 was obtained with the Subaru Telescope IRCS using the AO system. We have detected strong Na i D absorption in high-redshift DLAs at z_{abs} = 1.062 and 1.181, confirming the presence of Na i, which was first reported for the rest-frame UV Na i D_{3303.3, 3303.9} doublet by Petitjean et al. This is the first detection of Na i D in a high-redshift (z > 1) DLA. We have also detected a new Na i component in the z_{abs} = 1.062 DLA and four new components in the z_{abs} = 1.181 DLA. Using an empirical relationship between Na i and HI column density, we found that all components have large HI column density (log N_{HI} [cm^{-2}] ≥ 20.3), so each component is classified as DLA absorption. We also detected strong Na i D absorption associated with a Mg II system at z_{abs} = 1.173. Because no other metal absorption lines were detected in this system at the velocity of the Na i absorption in previously reported optical spectra, we infer that this Na i absorption cloud probably appeared in the line of sight toward the QSO after the optical observation. This newly found cloud is likely to be a DLA based on its large estimated HI column density. We found that the N_{Na i}/N_{Ca ii} ratios in these DLAs are systematically smaller than those observed in the Galaxy; they are more consistent with the ratios seen in the LMC. This is consistent with dust depletion generally being smaller in lower metallicity environments. However, all five clouds of the z_{abs} = 1.181 system have a high N_{Na i}/N_{Ca ii} ratio, which is characteristic of cold dense gas. We tentatively suggest that the host galaxy of this system may be the most significant contributor to the gravitational lens toward APM 08279+5255.

1. INTRODUCTION

Damped Lyα systems (DLAs) comprise a class of the QSO absorption line systems characterized by high HI column density greater than 2 × 10^{20} cm^{-2} (Wolfe et al. 1986). DLAs are one of the strongest probes for examining the evolution of metallicity and dust depletion in gaseous components of high-redshift galaxies (e.g., Pettini 2004). Since there is a well-established correlation between N_{Na i} and N_{H i} (Ferlet et al. 1985; Bowen et al. 1995), Na i absorption, which has been observed extensively in the Galaxy, holds the potential to estimate N_{HI} for individual clouds in DLAs, which usually cannot be precisely measured because of heavy blending of HI absorption. Moreover, the column density ratio of Na i to Ca ii provides a useful indicator of the degree of dust depletion of ISM clouds (e.g., Welsh et al. 1990; Crawford 1992; Bertin et al. 1993; Sembach et al. 1993; Price et al. 2001; Crawford et al. 2002) because sodium is hardly depleted from gas onto dust, while calcium can be heavily depleted (Savage & Sembach 1996).

The main absorption lines of Na i are the optical λ5891, 5897 D doublet and the ultraviolet λ3303.3, 3303.9 doublet. Observations exploiting the Na i D doublet hold the greater promise for comprehensive studies using Na i due to two important advantages: (1) the oscillator strength of the Na i D transitions is ~70 times greater than that of the Na i UV transitions (Morton 2003), and (2) Na i D absorption rarely overlaps with other metal absorption lines because the wavelengths of the Na i D doublet are significantly redder than most other metal lines. Thus, Na i UV doublets can be detected only in the highest column density systems toward the brightest QSOs. Weak Na i absorption systems are more likely to be detected with the Na i D doublet. However, observations of Na i D in high-redshift DLAs require near-infrared high-resolution spectroscopy because the rest-frame optical wavelengths are redshifted into the near-infrared. The advent of high-sensitivity and high-resolution spectroscopy in the near-infrared with 8 m class telescopes has enabled us to undertake such observations (e.g., Kobayashi et al. 2002, 2005; Kobayashi 2003).

As a first trial for detecting Na i D absorption lines at high redshift (z > 1), we observed the extremely bright zem = 3.911 gravitationally lensed QSO APM 08279+5255 (Irwin et al. 1998). There are two dominant gravitationally lensed images, “A” and “B,” with a separation of 0′′38 and flux ratio of f_{B}/f_{A} = 0.77 (Ibata et al. 1999). A third faint image, “C,” was also reported by Ibata et al. between A and B, with a separation of A – C = 0′′15 and flux ratio f_{C}/f_{A} = 0.18. Petitjean et al. (2000) reported...
probable faint Na i UV doublet absorption associated with the $z_{\text{abs}} = 1.062$ and $1.181$ DLAs in optical HIRES (Vogt et al. 1994) spectra obtained by Ellison et al. (1999a, 1999b). For both systems, Petitjean et al. concluded (1) $\log N_{\text{HI}} \sim 21$, (2) metallicity of $0.3–1.0 Z_{\odot}$, (3) dust-to-metal ratio about half that of the Galaxy, and (4) a temperature of around a few hundred kelvins.

In this paper, we present near-infrared 1.18–1.35 $\mu$m spectra of APM 08279+5255 with a resolution of about 50 km s$^{-1}$. The spectra were obtained with the Infrared Camera and Spectrograph (IRCS) using the adaptive optics (AO) system at the Japanese Subaru Telescope. The AO improved the FWHM of both images A and B such that the spectra of A and B were marginally separated. However, we combined the spectra of images A and B in order to maximize the signal-to-noise ratio and to compare our results with those by Petitjean et al. (2000). We will publish A-B separated spectra elsewhere. This paper is structured as follows: In § 2, we describe the IRCS observations and data reduction of APM 08279+5255. In § 3, we present the Na i D absorption lines and the fitting results for the $z_{\text{abs}} = 1.062$, 1.173, and 1.181 systems. We discuss our results and conclusions in § 4.

2. OBSERVATION AND DATA REDUCTION

Near-infrared 1.18–1.35 $\mu$m spectra of APM 08279+5255 were obtained on 2001 December 25 UT, during the scientific commissioning run of the IRCS instrument. IRCS is a Cassegrain mounted 0.9–5.5 $\mu$m near-infrared camera and spectrograph (Takami et al. 1998; Kobayashi et al. 2000) with an AO system (Takami et al. 2004) on the 8.2 m Subaru Telescope (Iye et al. 2004) located on Mauna Kea, Hawaii.

The Subaru AO system uses a curvature wave front sensor with 36 control elements to compensate for a distorted wave front due to the Earth’s atmosphere. For an $R \sim 11$ wave front reference star under excellent observing conditions, the AO provides a stellar image with a Strehl ratio of $\sim 0.04$ and a FWHM of $\sim 0.07$ in the $J$ band (1.25 $\mu$m). The performance degrades with fainter reference stars. For these observations, we used APM 08279+5255 itself ($R \sim 15.6$) as the wave front reference star. We achieved a FWHM of 0.′′2 in the $J$ band, which is much narrower than the 0.′′5–0.′′6 for typical seeing conditions at the Subaru Telescope.

We used the cross-dispersed echelle mode of the IRCS, which provides a spectral resolution of 15 km s$^{-1}$ ($\lambda/\Delta \lambda \sim 20000$) with a 0.′′15 slit. The pixel scale is 0.′′075 ($\sim 7.5$ km s$^{-1}$) pixel$^{-1}$ across the slit and 0.′′060 pixel$^{-1}$ along the slit. The entire $J$ band (1.18–1.35 $\mu$m) was covered simultaneously in one IRCS exposure, with the cross-disperser in order 5 and the echelle in orders 42–48. Although the FWHMs of the images were good throughout the observing time (about 0.′′2–0.′′5 in the $J$ band), we used a wider slit (0.′′6) to maximize throughput. Thus, the spectral resolution was determined by the average image size $\sim 0.′′5$, and the resulting spectral resolution was $\sim 50$ km s$^{-1}$ ($\lambda/\Delta \lambda \sim 6000$) in the observed wavelength range.

The slit length was 3′′8, and the position angle was set to 32° so that both the lensed images A and B were in the slit. The telescope pointing was nodded along the slit by about 2′′ for each 600 s exposure for sky background and dark subtraction. Because of the fine pixel scale needed for AO images and the high spectral resolution, it is impossible to reach the background limit in 600 s exposures, which are required to be less than the time variation of the sky OH emission. Eight sets of data were obtained, resulting in a total exposure time of 9600 s. Spectra of bright telluric standard stars (HD 92728: A0 Vs) at similar air mass were obtained in a similar fashion.

All the data were reduced following standard procedures using the IRAF$^9$ noao.imred.echelle package, including sky subtraction (subtraction of two frames), flat-fielding (halogen lamp with an integrating sphere), and aperture extraction. Argon lamp spectra that were taken at the end of the observing night were used for vacuum wavelength calibration. A heliocentric correction of 9.64 km s$^{-1}$ was applied to the vacuum wavelength calibrated spectra.

3. RESULTS

In Figure 1, we present the 1.18–1.35 $\mu$m spectrum of APM 08279+5255. The raw spectrum was smoothed with a 3 pixel ($\sim 20$ km s$^{-1}$) boxcar function for presentation. Na i D absorption lines from the $z_{\text{abs}} = 1.062$ and 1.181 DLAs are clearly seen. Several velocity components can be seen in the Na i D absorption lines from the $z_{\text{abs}} = 1.181$ DLA. In addition, Na i D absorption lines associated with the $z_{\text{abs}} = 1.173$ Mg ii system (Petitjean et al. 2000) are detected. This doublet absorption line was identified as Na i D lines because other metal lines of other absorption systems listed in Ellison et al. (1999a, 1999b) cannot account for these two absorption features.

We fit Voigt profiles to the Na i D absorption features assuming the component velocities identified by Petitjean et al. (2000) from metal absorption lines in the optical spectra by Ellison et al. (1999a, 1999b). The column density, Doppler width, and redshift of each component were evaluated using VPGUESS$^{10}$ and VPFIT$^{11}$ (Carswell et al. 1987). We fit two components for the $z_{\text{abs}} = 1.062$ system and five for the $z_{\text{abs}} = 1.181$ system. The absorption profiles are dominated by the instrument profile, which is almost identical to the Gaussian width FWHM $\sim 50$ km s$^{-1}$.

For the $z_{\text{abs}} = 1.181$ system, there is no a priori information on velocity components, unlike for the other systems. In addition, there are several adjacent hot pixels on the right side of the Na i 5897 absorption line, which makes the fitting with multi-velocity components difficult. Those hot pixels were difficult to remove because of their proximity to the Na i absorption line (see the feature labeled with crosses in Fig. 4). Because of the above reasons, we performed only one component VPFIT (almost equivalent to a simple Gaussian fitting) for this system. The hot pixel regions were ignored for the fitting. In view of the statistical noise that can be estimated by point-to-point fluctuations on the continuum, the single component fitting is almost satisfactory.

The fitting results are summarized in Table 1. Figures 2, 3, and 4 show the velocity profiles and fitting results for the Na i D lines. Using atmospheric absorption lines in the object and standard spectra, we confirmed that the pixel shift along the dispersion direction was less than 1 pixel throughout the observing time. Therefore, the systematic uncertainty of the velocity is less than 7.5 km s$^{-1}$. Although the column densities and the Doppler widths could not be directly determined because of insufficient instrumental spectral resolution, they can also be constrained by the doublet ratio [i.e., equivalent width ratio $W(5891)/W(5897)$]. As the doublet ratio approaches unity, uncertainty in column density increases because the column density and Doppler width become degenerate for a fixed equivalent width.

$^9$ IRAF is distributed by the National Optical Astronomy Observatory, which is operated by the Association of Universities for Research in Astronomy, Inc., under cooperative agreement with the National Science Foundation.

$^{10}$ VPGUESS is a graphical interface to VPFIT written by Jochen Liske; see http://www.eso.org/~jliske/vpguess.

$^{11}$ VPFIT is a Voigt profile fitting package provided by Robert F. Carswell; see http://www.ast.cam.ac.uk/~rfc/vpfit.html.
Fig. 1.—Detected Na i D absorption lines at $z_{\text{abs}} = 1.062$ (left) and $z_{\text{abs}} = 1.173$ and 1.181 (right). Vertical axis is normalized flux to the continuum level and horizontal axis is local-frame wavelength in both panels. The spectrum was smoothed with a 3 pixel ($\sim 20$ km s$^{-1}$) boxcar function. Longer lines indicate Na i D $\lambda 5891$, while shorter lines indicate Na i D $\lambda 5897$. The left spectrum is noisier than the right one because the Na i D absorption lines at $z_{\text{abs}} = 1.062$ were located on the edge of the detector where the detector noise is significantly larger. The bottom panels show the telluric absorption spectrum calculated with ATRAN package software (Lord 1992).

- **a** The velocity zero point is set to $z = 1.06230$, 1.17270, and 1.18070 for the three systems, respectively.
- **b** There is a systematic uncertainty, which is less than $\sim 7.5$ km s$^{-1}$. See text for details.
- **c** We estimated the velocity with an accuracy of 5 km s$^{-1}$ from Figs. 7 and 8 of Petitjean et al. (2000) by eye because Petitjean et al. (2000) do not list the velocities.
- **d** There is an additional systematic uncertainty of about 1 dex because the gravitationally lensed images are not resolved. See text for details.
- **e** There is an additional systematic uncertainty of about 0.3 dex because the gravitationally lensed images are not resolved. See text for details.
- **f** There is a possible significant systematic uncertainty because of the accidental overlap of the $z_{\text{abs}} = 3.502$ Mg i absorption line. See text for details.
Because the physical distance (∼1 kpc) between A and B at z ∼ 1 is much larger than the typical spatial scale of Na\textsc{i} clouds in our Galaxy (a few tens to several thousands of AU; e.g., Price et al. 2001), the images A and B are most likely covered unequally. This introduces an additional systematic uncertainty in the inferred properties of the Na\textsc{i} clouds. An estimation of the systematic uncertainty depends on the saturation level of the Na\textsc{i} absorption lines in the A+B combined spectrum. It can range from ∼0.3 dex for a moderately saturated case to ∼1 dex for a heavily saturated case. The estimated systematic uncertainty for each component is shown in Table 1.

Because the resolution of the optical spectrum is higher than that of our near-infrared spectrum, the estimated redshift of each component by Petitjean et al. (2000) should be more accurate than ours. Hereafter, we use the velocities reported by Petitjean et al. (2000) for our discussion of each component, except for the newly identified components from our spectrum.

3.1. DLA at z_{\text{abs}} = 1.062

In this system, we found two Na\textsc{i} components at +53 and +108 km s\textsuperscript{-1}, which we identify as the components at +55 and +120 km s\textsuperscript{-1} by Petitjean et al. (2000). While Petitjean et al. found a Na\textsc{i} component only at +55 km s\textsuperscript{-1}, we newly identified a Na\textsc{i} component at +120 km s\textsuperscript{-1}. The estimated column densities are log N_{Na\textsc{i}} = 12.9 and 11.7, respectively. These are consistent with Petitjean et al., who detected the former component with a similar column density, but not the latter component to an upper limit of log N_{Na\textsc{i}} < 12.8.
3.2. DLA at $z_{\text{abs}} = 1.181$

In this system, we found five Na i components. We identified the three components at $-99$, $-75$, and $+48$ km s$^{-1}$ as the components at $-105$, $-80$, and $+40$ km s$^{-1}$, respectively, reported by Petitjean et al. (2000). While Petitjean et al. found a Na i component only at $-80$ km s$^{-1}$, we newly identified Na i components at $-105$ and $+40$ km s$^{-1}$. We identified another two new Na i components at $+4$ and $+101$ km s$^{-1}$, which were not identified in Petitjean et al., probably due to contamination by other absorption lines. The estimated column density of the $-80$ km s$^{-1}$ component is $\log N_{\text{Na i}} = 12.5$, which is not consistent with Petitjean et al. However, our evaluation of the column density of the $-80$ km s$^{-1}$ component is not so robust because Mg ii $\lambda$2852 absorption associated with a Mg ii absorption system at $z_{\text{abs}} = 3.502$ (S. Kondo et al. 2006, in preparation) overlaps with the Na i D $\lambda$5891. The estimated column density of the $-105$ km s$^{-1}$ component is $\log N_{\text{Na i}} = 12.0$, which is consistent with the upper limit of $\log N_{\text{Na i}} < 12.4$ found by Petitjean et al.

3.3. Mg ii System at $z_{\text{abs}} = 1.173$

In this system, we found a Na i component at $+204$ km s$^{-1}$. Petitjean et al. (2000) did not find any metal absorption lines at this velocity. The detected Na i absorption line probably arises in a cloud that was previously not in front of the quasar at this velocity. We discuss the details of this newly identified component in § 4.2. We could not detect Na i absorption lines associated with the four components around 0 km s$^{-1}$ reported by Petitjean et al., probably because of their low Na i column density.

4. DISCUSSION

4.1. H i Column Densities of Each Velocity Component

Following Petitjean et al. (2000), we estimated $N_{\text{H i}}$ for all components using the empirical relationship $\log N_{\text{H i}} = 6.688 \times \log N_{\text{Na i}} + 12.16$ ($11.6 < \log N_{\text{Na i}} < 13.4$) (Sembach et al. 1993; Diplas & Savage 1994; Bowen et al. 1995) established for Galactic interstellar absorption clouds. In Table 2, we summarize our results for $N_{\text{H i}}$. While this empirical relationship does not hold for $\log N_{\text{Na i}} < 11$ (Welty et al. 1994; Wakker & Mathis 2006).

|        | +4   | 11.7 ± 0.5$^c$             | 20.2 ± 0.3$^c$             | ...                    | ...                    |
|        | +40  | 12.0 ± 0.1$^c$             | 20.4 ± 0.1$^c$             | ...                    | ...                    |
|        | +101 | 12.2 ± 0.2$^c$             | 20.5 ± 0.1$^c$             | ...                    | ...                    |

$^a$ Velocities from figures in Petitjean et al. (2000). There is a systematic uncertainty, which is less than $\sim 7.5$ km s$^{-1}$. See text for details.

$^b$ There is an additional systematic uncertainty of about 1 dex because the gravitationally lensed images are not resolved. See text for details.

$^c$ There is an additional systematic uncertainty of about 0.3 dex because the gravitationally lensed images are not resolved. See text for details.

$^d$ There is a possible significant systematic uncertainty. The value shown here is after removal of the contamination from the Mg ii absorption at $z_{\text{abs}} = 3.502$. 

---

**Fig. 4.—Velocity profile of metal lines from $z_{\text{abs}} = 1.173$ system. Notation is the same as that in Fig. 2. Horizontal axis shows the heliocentric velocity from $z = 1.1727$. Bottom three panels show the velocity profiles of Ca ii $\lambda$3934, Mg ii $\lambda$2803, and Mg i $\lambda$2852 absorption lines obtained with HIRES. Vertical dashed lines mark velocity components ($V = -20, 0, +35, \text{and } +50$ km s$^{-1}$) found by Petitjean et al. (2000) and that ($V = +204$ km s$^{-1}$) newly found with Na i D data. Spurious features labeled with crosses on the right side of $\lambda$5897 absorption are due to hot pixels. See text for details.
2000; Wakker 2001) or for log \( N_{\text{Na}^i} > 12.9 \) (Ferlet et al. 1985), the column densities of all the detected components are within the appropriate range of this relationship. The estimated \( N_{\text{H}^i} \) in various components, however, is subject to systematic uncertainties related to the following issues:

1. **Low metallicity.**—It is likely that the column density ratio \( N_{\text{Na}^i}/N_{\text{H}^i} \) is in proportion to the metallicity. Vladilo et al. (1993) found that the column density ratio in the Large Magellanic Cloud (LMC) decreases in proportion to the metallicity (~0.3 Z; Peimbert & Torres-Peimbert 1974; Pagel et al. 1978). Because the metallicities of the \( z_{\text{abs}} = 1.062 \) and 1.181 DLAs are estimated to be in the range of 0.3–1.0 Z (Petitjean et al. 2000), it is appropriate to interpret the estimated \( N_{\text{H}^i} \) in these systems as lower limits.

2. **Contamination from a metal absorption line of other redshift.**—We could not evaluate the reliable column density of the –80 km s\(^{-1}\) component in the \( z_{\text{abs}} = 1.181 \) system because Mg \( i 2852 \) absorption associated with a strong Mg \( ii \) system at \( z_{\text{abs}} = 3.502 \) (S. Kondo et al. 2006, in preparation) is blended with the Na \( i D 5891 \) absorption. Assuming the correlation \( N_{\text{Na}^i}/N_{\text{H}^i} = -0.73 \log N_{\text{Na}^i} + 7.6 \) (Churchill et al. 2003b) and the same Doppler width (\( b = 13.7 \) km s\(^{-1}\)) as the Mg \( ii \) absorption lines, we estimated the equivalent width of the Mg \( ii 2852 \) absorption. The H \( i \) column density of this component was estimated after removing this contamination from Mg \( i \), and this introduced systematic uncertainty. Even after removing the contamination, there still is another large uncertainty because the resulting doublet ratio of the Na \( i \) absorption lines is close to unity.

3. **Coverage of gravitationally lensed images A and B.**—As stated above, it is likely that the Na \( i \) clouds do not equally cover the gravitationally lensed images A and B. Thus, the estimated Na \( i \) column density is uncertain as described in §3. The estimated \( N_{\text{H}^i} \) varies accordingly.

While Petitjean et al. (2000) suggested that there are 40 and 20 small clouds in the \( z_{\text{abs}} = 1.062 \) and 1.181 systems, respectively, our results show that there are at least two and five high column density clouds in the systems, respectively. Most interestingly, we find that each cloud in the \( z_{\text{abs}} = 1.181 \) system has a H \( i \) column density that is classified as a DLA. This is the first indication of an absorber in which the individual clouds are each of such high column density. This is in contrast to the findings of Churchill et al. (2003a), who constrained the size of DLA clouds be less than 25 pc in the lensed QSO 0957+561 A,B and inferred that only one of the clouds gave rise to the DLA H \( i \) column density. This would suggest that the \( z_{\text{abs}} = 1.181 \) DLA, having \( N_{\text{H}^i} \approx 21.2 \), may be probing a very massive and large underlying structure (see, for example, Turnshek et al. 2004).

### 4.2. Detection of a New DLA at \( z_{\text{abs}} = 1.173 \): Proper Motion of a Cloud of a Few Hundred AU?

We have detected a new component at +204 km s\(^{-1}\) associated with the \( z_{\text{abs}} = 1.173 \) Mg \( ii \) absorption system. Based on scaling from the high Na \( i \) column density, this system is probably a DLA rather than a Lyman limit Mg \( ii \) system (Petitjean et al. 2000). Therefore, this system might contribute to the gravitational lensing of the QSO, together with the other three DLAs, at \( z_{\text{abs}} = 1.062, 1.181, \) and 2.974, as suggested by Petitjean et al. Despite the large Na \( i \) column density, Petitjean et al. did not identify any metal lines for this velocity component in the optical Keck spectrum. Similarly, in a subsequent search, we also could not identify any Mg \( ii \), Mg \( i \), and Ca \( ii \) absorption lines for this component in the HIRES spectrum\(^{12}\) (see Fig. 4).

Because there is a time span of 3.6 yr between our observation and the optical observation in the local frame, or ~1.7 yr in the rest frame (\( z_{\text{abs}} = 1.173 \)) considering the effect of cosmological time dilation by a factor of \((1 + z_{\text{abs}})^{-1}\), it is probable that the newly identified cloud appeared in the line of sight toward the QSO within that time span. If the cloud is moving in a tangential direction in the sky with a velocity of ~400 km s\(^{-1}\), the travel distance is ~200 AU in ~1.7 yr in the rest frame. The assumed velocity is comparable to the combined velocity of the motion of clouds in high-redshift galaxies (~50–260 km s\(^{-1}\); Erb et al. 2003) and the proper motion of field galaxies, which should be smaller than the typical velocity dispersion of the cluster of galaxies (e.g., between ~500 and ~1000 km s\(^{-1}\); Gal & Lubin 2004). This sets the upper limit of the cloud size and is consistent with the size of the Na \( i \) clouds in the Galaxy, which ranges from a few to several thousand AU (e.g., Meyer & Blades 1996; Meyer & Lauroesch 1999; Welty & Fitzpatrick 2001; Andrews et al. 2001; Lauroesch et al. 2000; Lauroesch & Meyer 2003). Our result shows that we can catch the very small scale structures of the cold (~100 K) neutral gas component in high-z QSO absorption systems with the time variation of Na \( i \) absorption features. The observable spatial scale with this technique is much smaller than that with the observation of gravitationally lensed QSOs (see discussion in Ellison et al. 2004).

### 4.3. Dust Depletion and Chemical Uniformity in DLAs

The column density ratio \( N_{\text{Na}^i}/N_{\text{Ca}^{ii}} \) has often been used as a good indicator of the degree of dust depletion because calcium is hardly depleted from gas onto dust grains while calcium can be heavily depleted (Savage & Sembach 1996). In Table 3, we list the ratio \( N_{\text{Na}^i}/N_{\text{Ca}^{ii}} \) for each component. \( N_{\text{Ca}^{ii}} \) for the +120 km s\(^{-1}\) component at \( z_{\text{abs}} = 1.062 \) and for the +105 and –80 km s\(^{-1}\) components at \( z_{\text{abs}} = 1.181 \) are taken from Petitjean et al. (2000), while those for the +4, +40, and +101 km s\(^{-1}\) components at \( z_{\text{abs}} = 1.181 \) were evaluated\(^{13}\) using archived optical spectra (Ellison et al. 1999a, 1999b).

| System | \( V \) | \( \log N_{\text{Na}^i} \) | \( \log N_{\text{Ca}^{ii}} \) | \( \log (N_{\text{Na}^i}/N_{\text{Ca}^{ii}}) \) |
|--------|------|----------------|----------------|----------------|
| 1.062... | +50  | 12.9 ± 1.6\(^a\) | ... | ... |
|        | +100 | 11.7 ± 0.1\(^b\) | 11.7 ± 0.03 | -0.02 ± 0.1 |
| 1.181... | -100 | 12.0 ± 0.5\(^c\) | 11.33 ± 0.39 | 0.7 ± 0.6 |
|        | -75  | 12.9\(^d\) | 11.79 ± 0.35 | 1.1 |
|        | +4   | 11.7 ± 0.5\(^e\) | <11 | >0.7 |
|        | +40  | 12.0 ± 0.1\(^f\) | 11.4 ± 0.2 | 0.6 ± 0.1 |
|        | +101 | 12.2 ± 0.2\(^g\) | <11 | >1.2 |

\(^{a}\) There is an additional systematic uncertainty of about 1 dex because the gravitationally lensed images are not resolved. See text for details.

\(^{b}\) No measurement was possible due to the blending effects. See note of Table 2 in Petitjean et al. (2000).

\(^{c}\) There is an additional systematic uncertainty of about 0.3 dex because the gravitationally lensed images are not resolved. See text for details.

\(^{d}\) There is a possibly significant systematic uncertainty. The value shown here is after removal of the contamination from the Mg \( i \) absorption at \( z_{\text{abs}} = 3.502 \).

\(^{e}\) We evaluated the Ca \( ii \) column density at \( z_{\text{abs}} = 1.173 \) because the contaminating Mg \( ii \) absorption at \( z_{\text{abs}} = 3.502 \) is blended.

\(^{f}\) We evaluated the Ca \( ii \) column density for those systems using VIPFIT. We also evaluated Ca \( ii \) column densities for the +120 km s\(^{-1}\) component at \( z_{\text{abs}} = 1.062 \) and the –105 and –80 km s\(^{-1}\) components at \( z_{\text{abs}} = 1.181 \) and confirmed that our fitting results are consistent with those estimated by Petitjean et al. (2000).
is less than 20%. A red filled square shows the data for the Black and blue symbols show the data for our Galaxy (Vallerga et al. 1993) and the LMC (Vladilo et al. 1993), respectively. The uncertainty of those data is less than 20%. A red filled square shows the data for the $V = -80$ km s$^{-1}$ velocity component at $z_{\text{abs}} = 1.81$, whose uncertainty is not shown because it could not be accurately estimated due to the accidental overlap of the $z_{\text{abs}} = 3.502$ Mg i absorption line (see text).

We estimated the $3 \sigma$ upper limit of $N_{\text{Ca II}}$ for the +4 and $+101$ km s$^{-1}$ components at $z_{\text{abs}} = 1.81$ because no Ca ii absorption line was detected in the optical spectra. In Figure 5, we show a $\log (N_{\text{Na I}}/N_{\text{Ca II}}) - \log N_{\text{Ca I}}$ plot for the DLAs, as well as Na i clouds in the Galaxy (Vallerga et al. 1993) and in the LMC (Vladilo et al. 1993).

We found that $\log (N_{\text{Na I}}/N_{\text{Ca II}})$ in these DLAs is systematically smaller than those in the Galaxy but similar to those in the LMC (Welty et al. 1999), suggesting that dust depletion is generally smaller in a lower metallicity environment. Our results are consistent with the results of Vladilo (1998), who have shown that dust-to-metal ratios of DLAs are similar to that of the LMC but smaller than that of the Galaxy, using the column density ratio of zinc to chromium.

It is also interesting to consider the uniformity in the $N_{\text{Na I}}/N_{\text{Ca II}}$ ratio across the $-200$ km s$^{-1}$ velocity spread of the $z_{\text{abs}} = 1.81$ DLA. As presented in Table 3, it would appear that the ratios are consistent with being uniform with component velocity, although there is large uncertainty in this statement. If so, this is consistent with the findings of Prochaska et al. (2003a) and Churchill et al. (2003a), who reported uniform column density ratios as a function of velocity in DLAs. It was also found by Churchill et al. that the uniformity is spatial, at least on the scale of 200 pc. If the $N_{\text{Na I}}/N_{\text{Ca II}}$ ratio is more-or-less constant across the profiles in the $z_{\text{abs}} = 1.81$ DLA, it would suggest that the chemical, ionization, and dust depletion levels are uniform across the clouds.

4.4. The $z_{\text{abs}} = 1.81$ System: Cold Dense Gas Clouds near the Center of a Galaxy?

All five components of the $z_{\text{abs}} = 1.81$ system have $\log (N_{\text{Na I}}/N_{\text{Ca II}}) > 0$, which is a characteristic of cold dense gas in the Galaxy (known as the “the Routly-Spitzer effect”; e.g., Routly & Spitzer 1952; Vallerga et al. 1993; Sembach & Danks 1994). Because there are five cold dense and very high column density clouds for the $z_{\text{abs}} = 1.81$ system, we suggest that the line of sight may be passing near the center of the host galaxy. The relatively high metallicity of this system ($0.3 – 1.0 Z_{\odot}$; Pettitjean et al. 2000) compared to that typical of $z \sim 1$ DLAs ($\sim 0.1 Z_{\odot}$; Prochaska et al. 2003b) also supports the above idea because the metallicity of DLA absorption is higher in the inner region galaxies because of a metallicity gradient (Chen et al. 2005). Therefore, the host galaxy of this system might be the most significant contributor to the gravitational lens among four DLAs toward APM 08279+5255. Note that some DLAs were observed to have an impact parameter larger than 65 kpc (Churchill et al. 2005) and the above argument should be taken with caution.

We are grateful to all of the IRCs and AO team members and the Subaru Telescope observing staff for their efforts, which made it possible to obtain these data. We are also grateful to Ellison et al. for making their excellent data available on the World Wide Web and to Jochen Liske for kindly answering our questions about VPGUESS. We thank the National Astronomical Observatory of Japan for their financial support and encouragement for the construction of the IRCs and AO. Y. M. is financially supported by the Japan Society for the Promotion of Science (JSPS).
