Adoptive transfer of tumor-infiltrating lymphocytes in melanoma: a viable treatment option

Maartje W. Rohaan 1, Joost H. van den Berg 2,3, Pia Kvistborg 3 and John B. A. G. Haanen 1,3*

Abstract

The treatment of metastatic melanoma patients with autologous tumor-infiltrating lymphocytes (TIL) shows robust, reproducible, clinical responses in clinical trials executed in several specialized centers over the world. Even in the era of targeted therapy and immune checkpoint inhibition, TIL therapy can be an additional and clinically relevant treatment line. This review provides an overview of the clinical experiences with TIL therapy thus far, including lymphodepleting regimens, the use of interleukin-2 (IL-2) and the associated toxicity. Characteristics of the TIL products and the antigen recognition pattern will be discussed, as well as the current and upcoming production strategies, including the selective expansion of specific fractions from the cell product. In addition, the future potential of TIL therapy in melanoma and other tumor types will be covered.

Keywords: Melanoma, Adoptive cell therapy, Tumor-infiltrating lymphocytes, Immunotherapy, Lymphodepletion, Interleukin-2, Antigen recognition, Combination therapy

Background

The incidence of malignant melanoma has been on the rise over the past few decades. An estimated 351,880 new cases of melanoma have been diagnosed worldwide in 2015 with a mortality rate of 17% [1]. Less than a decade ago, the treatment options were very limited for patients with advanced stage disease and the 5-year overall survival (OS) was only 9–28% [2, 3]. With the development of immunotherapies as well as targeted therapies, the OS has significantly improved. Currently, the known 3-year OS for patients with stage IV melanoma reaches up to 58% [4]. In spite of these recent clinical successes, still a large group of patients fail to respond to therapy or progress after initial response, which brings the need for additional treatment modalities.

One such additional treatment option is adoptive cell therapy (ACT) with tumor-infiltrating lymphocytes (TIL). ACT with TIL has been of growing interest as an anti-cancer treatment in the past decade. This therapy consists of the outgrowth of tumor resident T cells from tumor material, their expansion ex vivo and transfer back into the same patient after a lymphodepleting preparative regimen [5]. In many studies, the infused T cells are supported by high-dose interleukin-2 (HD IL-2) to facilitate engraftment of the cells.

After the first demonstration of promising clinical effects of TIL in melanoma patients in the 90’s and the beginning of the new millennium by the Surgery Branch of the National Institutes of Health (SB, NIH, Bethesda, Maryland, US) [6–8], multiple clinical trials at different sites over the world confirmed these results. In these trials, objective responses varying between 40 and 70% have consistently been observed [8, 9]. As the applicability and scope of ACT with TIL is broadening, the optimization of TIL production, including selection of T cell subsets, and adjustment of the clinical protocol, including the lymphodepleting preparative regimens and the role of IL-2 are of utmost importance. Of upcoming interest is also the potency of TIL transfer in adjuvant setting [10], as combination therapy [11], as well as its efficacy in other solid tumors [12–14].

In this review, we will provide an overview of the current state of ACT with TIL in melanoma, focusing on...
on clinical responses, production and treatment protocols, associated toxicity, as well as the future potential of TIL therapy as anti-tumor treatment.

**Current state of TIL treatment in malignant melanoma**

The first objective clinical responses with TIL treatment were seen in a series of phase I/II trials, all executed by Rosenberg and colleagues more than 20 years ago at the NIH, in which infusion of TIL was combined with lymphodepleting conditioning regimes and HD IL-2 [6–8]. Consistent objective response rates (ORR) up to 72% were reached with TIL therapy in several consecutive clinical trials, in which 10–20% of treated patients reached a complete remission (CR) and 40% of patients achieved durable clinical responses. These durable responses were predominantly seen in patients who achieved CR at an early time point and the chance for response did not seem to be influenced by progression upon prior systemic treatment [8, 9, 15–19]. Objective responses seemed to be associated with higher number of infused cells [18].

Originally, the conditioning non-myeloablative (NMA) regimen consisted of cyclophosphamide (60 mg/kg) for 2 days, followed by fludarabine (25 mg/m²) for 5 days. The infusion of TIL products followed >24 h after the final dose of fludarabine. Patients subsequently received HD IL-2 (720,000 IU/kg intravenously (i.v.) every 8 h up to 15 doses or until intolerance [6, 8, 16]. Other trials have been conducted with adjusted production protocols, different conditioning regimens, and IL-2 schedules, which will be discussed below.

The encouraging results of TIL therapy in melanoma have stimulated centers worldwide to conduct studies in order to reproduce and optimize this treatment. Focus for optimization was directed at cell fraction, preparative regimen and IL-2 dose. Additional file 1: Table S1 shows an overview of these studies. The conducted studies with TIL in patients with metastatic melanoma have predominantly been as first-line treatment or in patients with progression upon prior systemic immunotherapy. These treatments mostly consisted of chemotherapy with dacarbazine, interferon-α, IL-2, ipilimumab, an anti-CTLA-4 antibody, or combinations [8, 15, 16, 18, 19]. Treatment with PD-1 blockade, or an anti-PD-1-based combination, is now mostly first-line therapy in patients with advanced melanoma, showing an unprecedented 3-year overall survival around 50% [4]. The role of TIL as possible first-line therapy in combination with anti-PD-1 is currently subject of clinical trials, and one has to await the first results to estimate the additive effect of TIL and anti-PD-1. However, TIL therapy may be a potential option in patients with disease progression upon PD-1 blockade, as current treatment options for these patients is still very limited.

Whether TIL should be given in combination with anti-PD-1 or as a single treatment option is still an unknown. To provide evidence that TIL therapy is more effective than the current standard of care with anti-CTLA-4 (ipilimumab) for patients with advanced melanoma upon progression on up to one prior treatment, a multicenter randomized phase III trial is actively recruiting patients at the Netherlands Cancer Institute (NKI, Amsterdam, The Netherlands) and the Center for Cancer Immune Therapy (CCIT, Herlev, Denmark). The patients enrolled in this trial are randomized in a 1:1 ratio between ipilimumab and TIL treatment (NCT02278887).

Currently, the vast majority of patients that are enrolled in this trial have progressed on anti-PD-1 treatment. In addition to this phase III trial, another 22 clinical trials worldwide are being performed with TIL therapy in melanoma to evaluate the optimal treatment form, with varying TIL production and treatment protocols, and as combination therapy. For a complete overview of these clinical trials, see Table 1.

**Evidence for lymphodepleting preparative regimens**

The necessity of temporary lymphodepleting preconditioning before TIL infusion remains an important aspect in ACT with TIL. The first evidence for the need of lymphodepletion with either chemotherapy or total body irradiation (TBI) was demonstrated in murine models, where improved response rates were seen with TIL after lymphodepletion [20, 21]. Lymphodepletion with either TBI or NMA chemotherapy is thought to improve the effector function of TIL in several ways. Firstly, data from several studies suggest that the endogenous subpopulation of CD4+CD25+ regulatory T cells (Tregs) capable of suppressing immune responses may be depleted [22]. Secondly, lymphodepletion of the host reduces the pool of endogenous lymphocytes competing with the transferred T cells for homeostatic cytokines, especially IL-7 and IL-15 [23]. These cytokines are produced by non-lymphoid sources in response to lymphopenia, where IL-7 is required for the proliferation and survival of T cells and IL-15 maintains and improves the proliferation of the T cells [24, 25]. Lastly, lymphodepletion is believed to generate “physical space” for the infusion product.

In 2002, the Surgery Branch of the NIH demonstrated the clinical importance of lymphodepletion before TIL infusion. In this study, 13 patients with metastatic melanoma were treated with cyclophosphamide 60 mg/kg/day for 2 days and fludarabine 25 mg/m²/day for 5 days prior to TIL infusion and achieved an ORR of 46% [7], which compared favorable to response rates of 31% without prior lymphodepletion [6]. In 2008, this same group examined the effect of intensifying the lymphodepleting regimen by adding TBI to the above mentioned...

NMA chemotherapy and improved clinical outcomes with this strategy. Patients were treated with cyclophosphamide and fludarabine with addition of either 2 Gy or 12 Gy TBI, with 25 patients in each cohort. Compared to the cohort treated solely with chemotherapy showing an ORR of 49%, addition of TBI with 2 Gy or 12 Gy improved these ORR to 52 and 72% respectively [16].

In a follow-up randomized trial, the additional benefit described above of TBI in addition to NMA chemotherapy for the ORR could not be confirmed. A total of 101 patients with metastatic melanoma were either treated with NMA chemotherapy as described above per standard protocol, or in combination with 1200 cGy TBI (TBI 2 Gy twice a day for 3 days) prior to TIL infusion. Clinical outcome was similar in both treatment arms, with durable CR seen in 24% of patients in both cohorts and no significant difference in ORR of 45 and 62% in patients pretreated with NMA chemotherapy alone or with the addition of TBI respectively (p = 0.11). Of note, addition of TBI did result in additional toxicity, namely thrombotic microangiopathy in 27% of patients [26].

Temporary lymphodepletion with chemotherapy, TBI or a combination thereof appear to have an additive effect on the efficacy of TIL therapy as described above. Nevertheless, the question remains what the optimal regimen is, in terms of both duration and depth of lymphodepletion and in terms of which drug(s) to use. Answers to these questions are not only relevant to further improve response rate to TIL therapy, but also to minimize toxicities, now predominantly consisting of transient pancytopenia and febrile neutropenia occurring in 37–96% of patients [18, 19].

To address these questions, the Sheba Medical Center, Israel, is currently conducting a phase II clinical trial exploring the efficacy of reduced intensity lymphodepletion using fludarabine 25 mg/m² for 3 days (instead of five per standard protocol and no addition of cyclophosphamide) followed by TBI (2 Gy single treatment for 1 day prior to TIL infusion (NCT03166397). This clinical trial is still recruiting and is expected to give more insight into the optimal lymphodepleting regimen prior to the infusion of TIL in melanoma patients.

The role of interleukin-2 in the current treatment protocol

Single agent IL-2 has received approval by the US Food and Drug Administration for the treatment of metastatic renal cell cancer and metastatic melanoma in 1992 [27] and 1998 [28] respectively. When used in combination with TIL, IL-2 is thought to enhance the anti-tumor response by continuous support of growth and activity of the infused TIL products. Studies suggest that IL-2 may enhance the inherent antitumor activity of CD8+ T cells and the cytolytic function of natural killer cells [29]. However, IL-2 is also associated with a variety of toxicities, some associated with capillary leak syndrome presented by edema, hypotension and reduced urine output within hours of infusion, but also fevers, rigors, myalgia and nausea. Most of these toxicities can be managed well by supportive measures [28]. However, so far no clear correlation between the number of IL-2 infusions and clinical response could be demonstrated. It is therefore worthwhile to reconsider the role of HD IL-2 administration in combination with TIL infusion.

A phase I trial at the NIH evaluated the anti-tumor effect of TIL therapy with varying IL-2 doses ranging from 0 to 720,000 IU/kg in 15 patients with metastatic melanoma. Patients receiving either low-dose (LD) IL-2 (72,000 IU/kg i.v. every 8 h up to 15 doses) (n = 3) or HD IL-2 (720,000 IU/kg i.v. every 8 h up to 12 doses) (n = 6) following NMA chemotherapy and infusion of TIL showed reduction in tumor volume. This effect was not seen in patients that did not receive any IL-2 (n = 6) [30]. Of importance, however, is that these findings are based on a small study and confirmation of these data would require a larger prospective trial. The CCIT, Herlev, Denmark, demonstrated clinical responses in patients with metastatic melanoma treated with lymphodepleting chemotherapy and TIL infusion followed by subcutaneous (s.c.) LD IL-2 injections (2 MIU for 14 days). Durable objective responses were seen in 2/6 (33%) patients and 2/6 (33%) patients showed disease stabilization [31]. In another phase I/II study by the same group, administration of intravenous IL-2 in a decrescendo regime also showed clinically significant responses with an ORR of 42%. In this trial, 25 patients with metastatic melanoma were treated with standard lymphodepleting chemotherapy and TIL infusion followed by 5 days of continuous infusion of IL-2 in a decrescendo manner, with 18 MIU/m² over 6, 12 and 24 h followed by 4.5 MIU/m² over 24 h for 3 days [18]. These data from the NIH and CCIT suggest that it might be possible to lower the dose of IL-2, without negatively affecting clinical outcome.

Currently, several clinical trials are being conducted to evaluate the clinical efficacy of these different IL-2 regimens in ACT with TIL, as presented in Table 1.

Toxicity

The most common toxicities during TIL therapy are due to the effects of the lymphodepleting preparative regimens and the subsequent IL-2 after TIL infusion [32]. TIL-related toxicity is less common, but patients may develop, mostly transient, dyspnea, chills and fever shortly after infusion of TIL. Other signs of toxicity develop later after infusion and may consist of melanoma associated autoimmune diseases such as vitiligo or uveitis, of which the latter promptly responds to topical corticosteroid treatment. This demonstration of autoimmune-like
toxicity does not seem to be significantly correlated with response to TIL therapy [19]. In general, autoimmune-like toxicity such as uveitis, hearing loss and vitiligo after TIL therapy is much less common compared to development of these side-effects following ACT with MART-1 or gp100 specific T cell receptor (TCR) gene therapy [33]. One plausible reason for this difference could be that TIL products consist of a more polyclonal T cell population targeting more and other antigens than the homogenous T cell population in the TCR gene therapy product.

Autoimmune toxicity due to TIL therapy is not always transient, as described by Yeh et al. In this case report, a patient undergoing TIL therapy developed severe autoimmune sequelae including diffuse erythematous full-body rash, persistent panuveitis and hearing loss. The patient was treated following preparative lymphodepletion with cyclophosphamide, fludarabine and TBI 12 Gy prior to infusion of $1.4 \times 10^{11}$ autologous TIL and 4 doses of HD IL-2. Biopsy of the rash showed dermal CD8+ T cell infiltrates. Flow cytometry of ex vivo expanded T cells from biopsies of the eyes demonstrated much higher percentages MART-1 MHC multimer-positive CD8+ cells compared to the peripheral blood after TIL therapy. The patient showed a durable CR of the metastatic melanoma 2 years after TIL therapy [34]. Although this case report suggests a positive correlation between the occurrence of autoimmune toxicity and response to ACT with TIL, such a correlation has not yet been demonstrated in larger patient cohorts.

**Characterization of TIL products**

The clinical efficacy of TIL therapy is greatly dependent on the specific quality of T cells to recognize and eradicate the tumor cells. In previous trials using TIL therapy in patients with metastatic melanoma, a significant correlation was seen between clinical benefit and culture time, percentage of CD8+ and CD8+/CD27+ cells and the absolute number of infused tumor reactive T cells in the infusion product [8, 17, 18, 35]. When autologous tumor material from patients is available, one can test the tumor reactivity of the generated TIL product in vitro by co-culture of the TIL with the autologous tumor cell lines or tumor digest, with as read-out the production of effector cytokines, such as IFN-γ and TNF-α, or degranulation markers (such as CD107) by the T cells. In our experience, up to 30% of the T cells in the infusion products are able to recognize autologous tumor material (unpublished data).

A substantial amount of cross-institutional effort has been made over the past decades to dissect what tumor-reactive T cells in TIL products recognize on human melanoma. To define the characteristics of potential T cell targets on melanoma, melanoma antigens can be separated in two major categories: Tumor-associated and tumor-specific antigens. The tumor-associated antigens include self-antigens with an aberrant expression in cancer, such as overexpressed (OE) antigens and cancer/testis (C/T) antigens, as well as tissue-specific antigens such as the melanoma differentiation (MD) antigens. These antigens are shared between subgroups of patients. The tumor-specific antigens include viral antigens in cancers associated with viral infections such as human papillomavirus (HPV) positive tumors where the onco-genes are viral proteins and the mutated antigens (neo-antigens), which arise as a consequence of DNA damage.

For decades, we have known that tumor-specific T cells in melanoma frequently recognize MD antigens. In particular MART-1 and gp100 are found to be recognized by the vast majority of TIL products. In previous work we have detected MART-1 specific T cell responses in 27 of 34 TIL infusion products, and gp100 specific T cell responses in 14 of these products [36]. Neo-antigens are conceptually very interesting T cell targets as they have the potential to be as foreign as for example, viral antigens because central tolerance is not expected. The first evidence for T cells recognizing neo-antigens was provided in a landmark study from 1995 by Wölfl et al., in which a T cell clone isolated from a melanoma patient was shown to recognize a mutated version of CDK4 [37]. At that point in time, technical limitations prevented a more systematic assessment of such T cell responses. Now, some 20 years later, technological advances in the ability to perform high throughput exome sequencing, together with the development of screening platforms for antigen-specific T cells, have made it realistic to investigate the frequency with which T cells recognize mutated antigens. Seminal work from the groups of Schreiber [38] and Sahin [39] provided proof of concept that these newly-developed technologies could be utilized to dissect T cell responses towards neo-antigens in their mouse models. Subsequently, work from multiple groups including ours, has cemented the paradigm that TIL frequently respond to neo-antigens in human melanoma. Furthermore, patients with tumors baring high mutational load are more likely to clinically benefit from immunotherapy than those with tumors with a low mutational burden. This has been demonstrated for lung cancer patients treated with anti-PD-1 therapy [40], melanoma patients treated with anti-CTLA-4 [41], and patients with mismatch repair deficient tumors across several cancer types with anti-PD-1 treatment [42, 43]. Based on these observations, it seems likely that T cells specific for neo-antigens play an important role in the responsiveness to immunotherapy. Direct evidence that neo-antigen specific T cells can be clinically relevant was provided by the group of Rosenberg and colleagues. They showed that patients can experience tumor regression upon adoptive
cell treatment with T cell products enriched for neo-antigen specific T cells [44]. In addition, we have detected multi neo-antigen directed T cells in our in-house produced TIL products (van den Berg et al., manuscript in preparation). Together, these findings make it attractive to enrich for neo-antigen specific T cell reactivity in TIL therapy to increase the response rate.

**TIL production**

In general, TIL production can be divided into two steps; initial outgrowth and rapid expansion (REP). Initial outgrowth starts with the excision of a melanoma metastasis of at least 2–3 cm, followed by transport to a Good Manufacturing Practice (GMP) production facility. This metastasis (or multiple smaller metastases) are cut into small pieces (of a few millimeters) or enzymatically digested into a single cell suspension. Fragments or digests are then cultured in the presence of IL-2 to allow the outgrowth of TILs. Initial outgrowth takes around 14 days for an average TIL patient (range at NKI 7 to 21 days), resulting in at least $50 \times 10^6$ TILs. During the outgrowth of a digest, tumor cells disappear from the cultures. The use of tumor fragments [17, 18] or digest [45, 46] seem not to influence the success rates of TIL outgrowth and/or clinical response.

During REP, which takes 14 days in the standard protocol, TILs are stimulated and further expanded to large numbers (between $1 \times 10^{10}$ and $2 \times 10^{11}$ cells). At the start of a REP, soluble anti-CD3 antibody, irradiated feeder cells (from autologous or allogenic source) in a 100–200 fold excess to the TILs, and IL-2 is added to the T cells. These irradiated feeders release growth factors into the culture which will accommodate massive TIL expansion, usually more than 1000-fold. During the last phase of the REP, a bioreactor (such as WAVE or Xuri, or gas permeable G Rex bottles) is required to allow culture of high cell densities [47]. The current success rate of TIL outgrowth is very high, although not 100%. The group at the NIH achieved to grow viable TIL in 75–85% from 93 melanoma patients [8] and the CCIT in Denmark recently reported a success rate of 97% (32 out of 33 TIL cultures from melanoma patients) [18].

Whether IL-2 is the most optimal cytokine for the outgrowth phase of TIL is debatable. It is known that IL-2 leads to the terminal effector state of T cells. This, in combination with the long production time of TIL, makes the final infusion product consist mainly of exhausted T cells. It would make sense to switch to homeostatic cytokines such as IL-7, IL-15 and IL-21 to generate a less differentiated T cell product. This could possibly result in longer engraftment and better tumor control in the recipient, as has already been observed in animal models [48]. However, since clinically active TIL production protocols are currently based on the use of IL-2, it is difficult to switch. Ideally, a clinical trial comparing different cytokine combinations for TIL outgrowth should be conducted to provide clarity about which cytokine strategy is superior.

**“Young” TILs**

In most early studies, several TIL cultures were established per patient and only the tumor reactive cultures were pre-selected for further outgrowth. Tumor reactivity was detected based on IFN-γ production upon in vitro co-culturing with autologous tumor material or HLA-matched tumor cell lines [8]. In later studies, this “selected” TIL strategy was exchanged for minimally cultured “young” TILs with an initial outgrowth phase < 20 days. During “young” TIL preparation, no pre-selection on tumor reactivity is used. All TILs that are grown are used for REP, making it easier to adapt [8, 49]. Interestingly, clinical response rates with “young” TILs are comparable with “selected” TIL [35, 50], which makes “young” TIL the current standard in the field.

Besides the ease, young TILs have two other major advantages; firstly, culture time is kept to a minimum. This is important since short culture times are associated with a better clinical response to TIL therapy [35]. Secondly, this optimization step results in a higher success rate to generate a clinical product, since for some patients no autologous tumor material or matching cell line is available, or no IFN-γ production could be observed.

**TIL selection**

TIL products are heterogeneous products. Not only do they differ in percentage CD8+ versus CD4+ T cells, but also in tumor reactivity and antigen specificity. As discussed above, only a fraction (up to 30% in our hands) of the total population is tumor reactive. In order to enhance tumor reactivity, TIL could be enriched using a selection marker. Selecting for a tumor reactive population beforehand could ideally also shorten culture time and lower the number of infused cells.

In 2010 Rosenberg and colleagues showed that PD-1 expression is high on melanoma reactive TIL and that this marker could be used to pre-select tumor reactive cells from the bulk TIL population using FACs or magnetic bead sorting. After enrichment, the PD-1 positive T cells were expanded in standard REP protocol. Using this PD-1 selection method, in three out of five tested patients, TIL products showed enhanced tumor reactivity compared to the PD-1 negative or non-selected population [51].

In another study, Powell et al. showed that CD137/4-1BB, an activation marker for CD8+ T cells, could be used to select tumor reactive TILs from melanoma samples. TILs were either FACs sorted or bead selected based on CD137 expression, and also these selected cells showed enhanced tumor reactivity compared to unselected TIL.
Both showed enhanced in vitro recognition of melanoma cells lines, based on IFN-γ production, and in vivo tumor control in a patient derived xenograft (PDX) mouse model was demonstrated [52]. Recently the Sheba Medical Center, Israel, demonstrated that CD137 selection could be performed with clinical grade compliant reagents. They expanded CD137 selected TILs in a large-scale manner to meet cell numbers required for patient treatment in a GMP facility. The increased anti-tumor effect was most prominent in an in vitro killing assay (using LDH release) and less prominent in IFN-γ release. Using this protocol, CD137 selected TILs were enriched for the recognition of both neo-antigens and shared antigens [45]. The Sheba Medical Center is currently running a trial using this CD137 selection strategy. Whether CD137 or PD-1 is the best marker to enrich for melanoma-reactive TIL is not known at present. Both methods will be further evaluated in clinical trials.

Our own group showed that the tumor reactivity of TIL products can be enhanced using clinical grade MHC streptamers to enrich for sub-populations of TIL with defined specificities. This strategy works for selection of TIL with both shared and neo-antigen reactivity. Importantly, the protocol can be performed under GMP conditions. A major challenge for clinical implementation of this strategy, is the requirement for knowledge of the peptide-specificity within the TIL product, before the MHC streptamers can be generated [53]. In addition, streptamers are only available for a limited number of HLA alleles.

Several groups showed that infusion of high numbers of CD8+ TIL is associated with a higher objective response [17, 35]. Both total number and percentage of CD8+ cells is significantly correlated with objective response (p = 0.0003 and p = 0.001 respectively) [17]. In addition, the observation was made that the presence of CD4+FoxP3+ Tregs is associated with lower clinical activity of TILs [54], suggesting that CD4+ cells in the infusion product might negatively influence clinical activity. This hypothesis was tested in a randomized controlled trial (RCT) with TIL in melanoma patients in which CD8+ enriched and unselected “young” TIL were compared. This study failed to show higher clinical activity of the CD8+ selected TILs [46].

**Genetic editing of TIL**

Current rapid developments in gene editing could also further enhance TIL therapy. These developments make it technically feasible to introduce potential beneficial receptors or molecules, or the other way around, knock-down/knock-out the ones that might be reducing the effect of TIL. Rosenberg and colleagues showed that Zinc Finger nuclease can be used to down regulate PD-1 in TIL, resulting in clinical grade TIL products with an enhanced effector function and cytokine production [55]. The currently widely used CRISPR-cas9 technology is expected to further increase the possibilities for gene editing of TIL. The MD Anderson Comprehensive Cancer Center, Houston, Texas, US, uses a lentiviral vector to transduce TIL with the chemokine receptor CXCR2, which could potentially improve tumor homing [56]. This strategy is currently evaluated in the clinic (see Table 1, NCT01740557). Transient, non-viral gene delivery by mRNA could also be used as alternative for the introduction of additional chemokine receptors in TIL [57]. All these technical developments open endless potential genetic improvements of the cell products.

An overview of the current TIL production protocol and potential improvements is shown in Fig. 1.

**TIL beyond monotherapy in stage IV melanoma**

So far, response rates to TIL treatment have been consistent between the many small or larger phase I/II clinical trials [8, 9]. In order to improve overall response and survival, TIL therapy could be combined with other immunotherapies [58]. In addition, TIL treatment for other malignancies than melanoma has become feasible as well, creating new treatment possibilities for these patients.

**TIL as adjuvant therapy**

Few studies with TIL treatment have been performed in patients with stage III melanoma. In a RCT conducted by Dreno et al., Nantes, France, 88 patients with stage III melanoma were treated with adjuvant TIL/IL-2 (n = 44) or IL-2 alone (n = 44) after surgery. Their hypothesis was that TIL treatment could be more efficacious in a setting with a minimal tumor burden. Patients receiving two infusions of 0.22–3.34 × 10^10 TIL at 6 and 10 weeks post-surgery followed by daily s.c. IL-2 injection (6 × 10^6 IU/m²) for 5 days a week with each TIL infusion, showed superior relapse free survival (RFS) and OS compared to the s.c. IL-2 only [10, 59, 60]. Importantly, TIL infusions were not preceded by NMA lymphodepletion and the number of cells infused were ~ 10-fold lower compared to ‘classical’ TIL. As s.c. IL-2 is not approved as adjuvant therapy for patients with stage III melanoma, it is difficult to put the outcome of this study in perspective.

**Combination therapy with TIL**

Recently, results have been published from a study in metastatic melanoma patients, who were treated with th combination of a targeted agent plus TIL. In this pilot study in 11 patients with BRAF V600E/K mutated melanoma, the BRAF inhibitor vemurafenib was given in conjunction with TIL. Patients were treated with vemurafenib for two weeks following metastectomy for the production of TIL, after which another lesion was resected. Patients...
were further treated according to standard protocol of lymphodepleting regimen, TIL infusion and IL-2. Vemurafenib was resumed after TIL infusion and continued for two years. Seven out of 11 patients (64%) showed an objective clinical response, two of whom had a durable response lasting up to three years [61]. These results are promising, however larger, randomized studies are needed to show the value of this approach in comparison to TIL alone. Currently, two clinical trials in which targeted therapy is being combined with TIL are actively accruing patients (NCT02354690, NCT01659151), see Table 1.

Treatment with the anti-CTLA-4 drug ipilimumab, was shown to heighten T cell infiltration into melanomas and to broaden the TIL response to these tumors [62]. In a recent clinical trial at the Moffitt Cancer Center, Tampa, US, 13 patients with metastatic melanoma were treated with ipilimumab in combination with standard TIL therapy. Patients received four doses of ipilimumab (3 mg/kg), starting two weeks before metastectomy for TIL harvest, one week after resection of a metastasis, followed by two and five weeks after conditioning chemotherapy. Five out of 13 patients (38.5%) showed an OR, four of which were durable, lasting up to one year and one patient developed a CR 52 months after this treatment [11]. Response rates seen in this trial were not different from those in other TIL trials. However, these data are the first to demonstrate the feasibility if combining TIL with immune checkpoint blockade.

Currently, several trials have been initiated combining TIL with PD-1 blocking agents (NCT03374839, NCT03475134, NCT03158935, NCT02652455, NCT02621021, NCT01993719), see also Table 1. Synergism from this combination may be expected as the ex vivo grown and expanded tumor-reactive TIL are often PD-1 positive [63] and prevention of the interaction between PD-1 on T cells and PDL-1 on tumor cells by anti-PD-1 therapy around the time of TIL infusion, may render these TIL more tumoricidal.

In addition, other immunotherapy modalities such as dendritic cell vaccination and (peg-)interferon, are being evaluated in a clinical setting combined with TIL therapy. See also Table 1 for details on current recruiting trials of combinations with TIL.

**TIL therapy for other solid tumor types**

For decades TIL treatment has been studied in patients with mostly metastatic cutaneous melanoma. Recently, investigators were also successful in growing out tumor reactive TILs from other tumor types, such as renal cell, breast and cervical cancer. In general, the tumor reactivity of TILs from these other tumors is lower when compared to melanoma [64]. The production and reactivity of TIL products for these other solid tumor types varies, amongst others, due to the heterogeneity in mutational load, and thus neo-antigens, and lymphocytic infiltration with variations of CD4+ and CD8+ T cells [65].

Promising OR of up to 35% have been seen in patients with metastatic uveal melanoma in an ongoing single-center, single-arm, phase II TIL study with 21 patients [66]. Despite the for this disease impressive ORR, the durability of these responses appeared short compared to what has been observed for cutaneous melanoma. A phase II trial has opened to confirm these results in a larger cohort, NCT03467516, see Table 1.

Recently, successful isolation, expansion and tumor recognition of TIL from renal cell carcinoma was reported. However, the reactivity of TIL was weaker and showed reduced functionality compared to TIL from melanomas [67]. Also in breast cancer, it is possible to isolate and expand TIL ex vivo under standard culture conditions. Four out of six randomly selected post-REP TIL samples were found to be reactive to the autologous tumor in vitro, which also showed functionality in vivo in a xenograft mouse model [12]. Recently, Stevanovic et al. demonstrated clinical responses upon TIL treatment in patients with refractory metastatic cervical cancer, with three of the nine treated patients showing objective tumor regression, two of which were durable. When possible, TILs were selected for HPV E6 and E7 reactivity, as the vast majority of cervical cancers harbor HPV oncoproteins that may act as immunotherapeutic targets for TIL [13]. Currently, a “basket” clinical phase II study is being conducted at the NIH in patients with a variety of metastatic disease, including digestive tract, breast, urothelial, ovarian and endometrial cancers, in order to provide information about rates of tumor regression when treated with TIL (NCT01174121).

**Limitations of TIL therapy and conclusions**

Despite the many promising beneficial effects, TIL therapy clearly also has its limitations. Firstly, TIL is the ultimate personalized immunotherapy, as for every individual patient a specific infusion product needs to be produced. Since infusion products have to be produced in a patient specific manner, costs are relatively high. However, non-commercial prices for TIL treatment are still considerably lower compared to treatment with checkpoint inhibitors, such as anti-CTLA-4, as described in an early cost-effectiveness model for TIL versus ipilimumab in patients with metastatic melanoma [68]. As discussed, success rates of TIL outgrowth vary between 75 and 97% [8, 18]. Therefore, there is a risk for every patient that treatment needs to be canceled. Production time of a TIL product is more than one month, which may be too long for some patients with rapidly progressive disease. In addition, highly specialized GMP facilities and production staff need to be in place, which
requires extensive investments and training. The development of computerized bioreactors could, at least in part, take over some of the handling by production staff in the near future, although the heterogeneity of the original material (tumor fragments or digest), makes it difficult to use a fully automated production process.

Overall, treatment with TIL shows great possibilities as anti-cancer therapy in melanoma and in the future,
possibly also in other solid tumors. However, TIL has not been approved as anti-cancer treatment yet by the regulatory authorities due to lack of results coming from sufficiently powered prospective RCTs. The currently recruiting phase III trial as discussed above (NCT02278887) should give the first direct proof of the effectiveness of TIL treatment compared to the current standard of care in patients with advanced melanoma unresponsive upon prior treatment.
