Robust Intrinsic and Extrinsic Calibration of RGB-D Cameras

Filippo Basso, Emanuele Menegatti, and Alberto Pretto.

Abstract—Color-depth cameras (RGB-D cameras) have become the primary sensors in most robotics systems, from service robotics to industrial robotics applications. Typical consumer-grade RGB-D cameras are provided with a coarse intrinsic and extrinsic calibration that generally does not meet the accuracy requirements needed by many robotics applications (e.g., highly accurate 3D environment reconstruction and mapping, high precision object recognition and localization, …). In this paper, we propose a human-friendly, reliable and accurate calibration framework that enables to easily estimate both the intrinsic and extrinsic parameters of a general color-depth sensor couple. Our approach is based on a novel two components error model. This model unifies the error sources of RGB-D pairs based on different technologies, such as structured-light 3D cameras and time-of-flight cameras.

Our method provides some important advantages compared to other state-of-the-art systems: it is general (i.e., well suited for different types of sensors), based on an easy and stable calibration protocol, provides a greater calibration accuracy, and has been implemented within the ROS robotics framework.

We report detailed experimental validations and performance comparisons to support our statements.

I. INTRODUCTION

The availability of affordable depth sensors in conjunction with common RGB cameras, often embedded in the same device (called RGB-D cameras), has provided mobile robots with a complete and instantaneous representation of both the appearance and the 3D structure of the surrounding environment. Many robotic tasks highly benefit from using such sensors, e.g., SLAM and navigation [1], [2], tracking [3], [4], object recognition and localization [5] and many others. While color information is typically provided by RGB cameras, there are many technologies able to provide depth information, e.g., time-of-flight (ToF) cameras, laser range scanners and sensors based on structured-light (SL). Even if there are many devices able to provide both color and depth data, as far as we know, there are no integrated, CMOS-like, imaging sensors able to provide both color and depth information yet. Most of the RGB-D sensors currently used in robotics applications (among others, the Microsoft Kinect 1 and Kinect 2, the Asus Xtion, and the Intel RealSense) are composed by an RGB camera and a depth camera rigidly coupled in the same frame.

In order to obtain a reliable and accurate scene representation, not only the intrinsic parameters of each camera should be precisely calibrated, but also the extrinsic parameters relating the two sensors should be precisely known. RGB-D devices are often factory calibrated, with the calibration parameter set stored inside a non-volatile memory. Unfortunately, the quality of such calibration is only adequate for gaming purposes. For instance, with a default setup, the acquired point clouds can suffer from a non accurate association between depth and RGB data, due to a non perfect alignment between the camera and the depth sensor. Moreover, depth images can suffer from an irregular geometric distortion and a systematic bias in the measurements. A proper calibration method for robust robotics applications is needed.

In this paper, we propose a novel, two-steps calibration method that employs a simple data collection procedure that only needs a minimally structured environment and that does not require any parameters tuning or a great interaction with the calibration software. The proposed method automatically infers the intrinsic calibration of the depth sensor by means of two general correction maps and, as a “side effect”, the rigid body transformation that relates the two cameras, i.e., the camera pair extrinsic calibration. We assume that the RGB camera has been previously calibrated using a standard method, e.g., [6], while for the depth sensor calibration, we employ a two components error model that includes a pixel-based distortion error along with a systematic error. Even if the principal target of the proposed method is structured-light RGB-D sensors, this two components error model is designed to be “technology-agnostic”, thus well generalizes also with sensors based on different technologies such as ToF cameras, as shown in error analysis and experiments.

The calibrated measurements are obtained employing two maps. We propose to represent the first map, used to correct the distortion error, by means of a set of functions of the depth measurements, iteratively fitted to the acquired data during a first calibration stage. The second map is obtained in a second stage of the calibration procedure, when we include the systematic error and the transformation between the sensors.

At this point we exploit the plane-to-plane constraints between color and depth data to align the two sensors and to infer the systematic error correction functions inside a non-linear optimization framework.

The main contributions of this paper are the following:

- A general and experimentally supported measurements error model, that well describes the error of different depth sensor types in an unified way.
- A spatial/parametric undistortion map that models in a compact and efficient way the distortion effect of structured-light depth sensors.
- A novel optimization framework that aims to estimate the
camera-depth sensor rigid displacement along with the parametric model which describes the systematic error on the depth measurements.

- An open source implementation of the proposed method, integrated inside the ROS (Robot Operating System) framework [7]. The code along with a tutorial of the calibration process is available on the following website: [http://iaslab-unipd.github.io/rgbd_calibration](http://iaslab-unipd.github.io/rgbd_calibration)

An exhaustive set of tests, proving the soundness of the proposed method, is reported. We also compare our method with other state-of-the-art systems, using the original implementations provided by their authors: our method appears to be more stable and able to provide the most accurate results. Finally, we report some experiments of a RGB-D visual odometry system applied to a mobile robot, where we show that the accuracy in the ego-motion estimation highly benefits from using RGB-D data calibrated with our system.

This paper is structured as follows. Related work is reviewed in Sect. II. In Sect. III the error on the depth values provided by the sensor is analyzed and discussed. Sect. IV gives a quick overview of the calibration procedure. The first calibration step is detailed in Sect. V while Sect. VI describes the second calibration step. The results of the calibration procedure and performance comparisons are reported in Sect. VII. Finally, some conclusions are reported in Sect. VIII.

### A. Basic Notations

We use non-bold characters $x$ to represent scalars, bold lower case letters $\mathbf{x}$ to represent vectors, with no distinction between cartesian coordinates and homogeneous coordinates. The coordinates of a point $p$ with respect to the coordinate frame $A$ are denoted by $^A p$; $^A T B$ denotes the homogeneous transformation matrix from the reference frame $A$ to the frame $B$, such that $^B \mathbf{x} = ^A T B^A \mathbf{x}$.

An RGB camera is denoted by $\mathcal{C}$ and it provides an RGB image $I_{\mathcal{C}}$; a depth sensor is denoted by $\mathcal{D}$ and it provides a depth image $I_{\mathcal{D}}$. From an RGB image of a scene that contains a checkerboard it is possible to extract the checkerboard corners $^C B$, where the superscript $^C$ explicit the fact that the corners are expressed in 2D pixel coordinates, i.e., $^C B = \{(u, v)_1, \ldots, (u, v)_n\}$. From a depth image $I_{\mathcal{D}}$ it is possible to generate a point cloud $^D C$, where the superscript $^D$ explicit the fact that the point cloud is expressed with respect to the coordinate frame $D$, i.e., $^D C = \{x_1, \ldots, x_m\}$.

### II. RELATED WORK

The availability in the market of affordable depth sensors (structured-light 3D sensors and time-of-flight cameras) has greatly increased the interest in depth sensor systems in both the robotics and computer vision communities. Several ToF cameras have been proposed over the years, and at the same time many researches began to analyze the sources of errors of such sensors [8], [9] and to propose suitable calibration methods to solve them [10]. A number of ToF-specific calibration methods [11], [12], [13] address the systematic nonlinear depth distortion that affects such sensor (often referred to as wiggle error), an error that depends only on the measured depth for each pixel [8]. Lindner et al. [11] proposed a method that combines intrinsic parameter estimation with wiggle and intensity adjustment, where the wiggle error has been faced by means a depth correction B-spline function. Other methods use regression to compensate such depth error: Kuznetsova and Rosenhahn [12] exploit a non-parametric Gaussian kernel regression, while Ferstl et al. [13] use Random Forest Regression: both these methods require to couple the depth sensor with an RGB camera. Kim et al. [14] presented an analysis of the measurement errors of a Mesa SwissRanger time-of-flight camera, highlighting the presence of two components: a random noise and a systematic depth error, consistent over time. Using this depth error model, they proposed a three-stages calibration procedure that aims to estimate both the intrinsic and extrinsic parameters of an array of sensors composed by both ToF and video cameras. Jung et al. [15] proposed to calibrate extrinsics and intrinsics of a color camera and a ToF camera pair by using a pattern with 4cm-diameter holes that can be simultaneously localized by both sensors. Unfortunately, the error models used in both methods are conceived for a SwissRanger-like sensor, and can not be easily adapted to depth sensors based on different technologies.

Early methods addressing the calibration of RGB-D pairs were intended to estimate only the extrinsic parameters that relate the two sensors. Mei and Rives [16] addressed the problem of finding the relative pose between a 2D laser range finder and a catadioptric camera by using a planar calibration pattern perceived from both sensors. Scaramuzza et al. [17] proposed to map 3D range information collected with a 3D tilting laser range finder into a 2D map (called Bearing Angle image) that highlighted the salient points of a scene thus the user could manually associate points between the two sensors in an easy way. The final extrinsic calibration was then obtained using a Perspective-n-Point (PnP) algorithm followed by a non-linear refinement step.

Depth sensors based on structured light technology have gained a great popularity thanks to the first version of Microsoft Kinect, an affordable and effective RGB-D pair based on active stereo matching that exploits a near-infrared random pattern projector. Early works on the Kinect sensor calibration [18], [19], [20], [21] were based on standard RGB camera calibration techniques. They used a checkerboard pattern to calibrate both the RGB and the IR cameras, often blocking the IR projector and illuminating the target with a halogen lamp in order to better highlight the checkerboard corners in the IR camera. Smisek et al. [20] showed that Kinect depth sensors are affected by a sort of radially symmetric distortion. To correct such distortion, they estimated a $z$-correction image built as the pixel-wise mean of the residuals of the plane fitted to the depth data. The $z$-correction image was subtracted from the $z$ coordinate of the cloud points to obtain the actual depth values. Unfortunately it is currently well known that
in the general case this distortion depends on the depth, i.e., becomes much stronger for increasing depths (e.g., see Sect. II). Also Zhang and Zhang [22] and Mikhelson et al. [23] exploited a checkerboard pattern but, differently from the previous approaches, they didn’t search for checkerboard corners in the IR image. Zhang et al. [22] used the fact that points on the checkerboard should be co-planar, and the plane equation can be estimated with the RGB camera. They also proposed to model the depth error of the Kinect sensor by treating the depth value \( z \) as a linear function of the real one \( z^* \), that is \( z = \mu z^* + \eta \). A limitation of this method comes from the fact that it requires to have a good initialization of the unknown parameters. Mikhelson et al. [23] extracted the structural corners from the point cloud derived from the depth images, in order to locate the checkerboard position also in the depth image plane. This approach assumes that the depth image is not affected by any distortion: as mentioned before, this assumption does not always apply for Kinect-like sensors. Moreover, from our experience, extracting structural corners from a point cloud is an operation that sometimes provides poor results.

Herrera et al. [24], [25] described a calibration method that exploits a checkerboard pattern attached to a big plane to calibrate two color cameras and a Kinect-like depth sensor. This method works directly on the raw data provided by the depth sensor (instead of on the metric data) and, alongside the camera-depth sensor relative displacement, it estimates a disparity distortion correction map that depends on the observed disparity. They estimated a coefficient for each pixel \( D(u, v) \in \mathbb{R} \) and two global coefficients \( \alpha_0, \alpha_1 \in \mathbb{R} \) such that the actual depth value \( z^* \) can be computed as

\[
z^* = z + D(u, v) \cdot \exp(\alpha_0 - \alpha_1 \cdot z).
\]

Moreover, they used the 4 corners of the checkerboard plane as the initial guess of the relative displacement between the cameras and the depth sensor. For short distances their approach seems to obtain good results, as reported also in [26], [27].

An improvement over the work of Herrera et al. is the one presented by Raposo et al. [28]. They proposed several modifications to the estimation pipeline that allow their algorithm to achieve a calibration accuracy similar to [25] while using less than 1/6 of the input frames and running in 1/30 of the time.

Canessa et al. [29], instead, proposed to model the depth error by means of a second degree polynomial for each pixel. In their work, authors first estimated the pose of a “virtual” depth sensor with respect to the RGB camera using an incandescent lamp bulb to light the checkerboard and make the depth map saturate in correspondence of the white squares. Then, they positioned a Kinect in front of a plane with a checkerboard attached and acquired a set of images from 0.6 m to 2 m. Finally, they fitted a second degree polynomial to the sample set of every pixel. Actually, the need of an incandescent lamp makes this system quite cumbersome.

Teichman et al. [30] proposed a completely different calibration approach for Kinect-like devices: the undistortion map is estimated by means of a SLAM framework, in an unsupervised way. Their algorithm estimates 6 depth multipliers, at 0, 2, . . . , 10 meters, and it corrects the depth measurements using a linear interpolation: to the best of our knowledge, this is one of the first approaches that proved to be able to correct depth data at more than 5 meters. The main drawback of their approach is the time it needs to reach a solution: the optimization procedure takes several hours to converge. Moreover, according to [27], it seems not to perform as well as [25] for short distances. Indeed, in [30] close-range measurements (i.e., less than 2 meters) are considered reliable and directly used in the SLAM pipeline to infer the geometry of the scene.

Fiedler et al. [31] investigated the influence of thermal and environmental conditions on the Kinect’s data quality. The experiments turned out that variations of the temperature and air draft have a notable influence on Kinect images and range measurements. They derived temperature-related rules to reduce errors in both the calibration and measurement process.

Recently, Di Cicco et al. [32] proposed a non-parametric, unsupervised intrinsics calibration method for depth sensors. The best plane fitted to the data is used as a reference, i.e., the average depth is considered reliable. A complete, discretized undistortion map for the depth data is estimated using a machine learning approach. In this approach the extrinsics calibration of a general RGB-D pair is not considered.

Staranowicz et al. [33] proposed an RGB-D pair calibration algorithm that uses a spherical object moved in front of the camera as a calibration pattern. A limitation of this method is that they focus on the estimation of the rigid displacement between the two cameras only, i.e., the depth error is not corrected.

In our previous work [33], we proposed a spatial/parametric undistortion map that models the distortion effect of Kinect-like depth sensors in a compact way. Our approach uses a calibration pattern similar to the one used in [24]: besides the undistortion map, we estimate the camera-depth sensor alignment along with a parametric model that well describes the systematic error of the depth measurements. Results were very promising, but this method could get stuck in a local minimum if the depth camera intrinsic parameters (focal lengths and central point) were poorly estimated. In this work we improve our previous method by addressing this limitation with a new, more general error model and a new calibration pipeline that refines also the depth camera intrinsic parameters. The calibration protocol employed in our method is inspired by [24] and [30], while our error model has been designed taking inspiration from both the error models presented in [14] and [29].

### III. Depth Error Analysis

In this section we introduce our depth error correction model, derived from an experimental analysis performed using two popular structured-light based depth sensors (the Microsoft Kinect and the Asus Xtion Pro Live RGB-D cameras) and a time-of-flight sensor (the Microsoft Kinect 2 RGB-D camera).
In this work we aim to remove both 1) and 2), while it is usually not possible to remove the quantization error 3) of SL sensors.\footnote{Continuous-wave based ToF sensors like the Kinect 2 measure the depth by means of a phase differences between an emitted sinusoidal light wave signal and the backscattered signals received. This phase is evaluated in closed-form using four equally spaced signals\footnote{In structured-light based depth sensors, the quantization error originates from the discrete nature of the disparity map used to extract the depth: this error is commonly mitigated by means of sub-pixel stereo matching algorithms, unfortunately these algorithms require to access low-level data that is usually not accessible from the user side.}.\footnote{The global error trend for the Kinect 2 sensor is plotted also in Fig. 22, where a more suitable scale has been used.}

The effect of 1) is to produce a local alteration of an object shape, while 2) is a systematic bias in the measurements.

In this work we aim to remove both 1) and 2), while it is usually not possible to remove the quantization error 3) of SL sensors.\footnote{Continuous-wave based ToF sensors like the Kinect 2 measure the depth by means of a phase differences between an emitted sinusoidal light wave signal and the backscattered signals received. This phase is evaluated in closed-form using four equally spaced signals\footnote{In structured-light based depth sensors, the quantization error originates from the discrete nature of the disparity map used to extract the depth: this error is commonly mitigated by means of sub-pixel stereo matching algorithms, unfortunately these algorithms require to access low-level data that is usually not accessible from the user side.}.\footnote{The global error trend for the Kinect 2 sensor is plotted also in Fig. 22, where a more suitable scale has been used.}

In the following, we refer to these error components as 1) distortion error and 2) global error, respectively. These errors in the case of SL sensors arise from a combination of two main sources: the radial and tangential lens distortion of the camera used for stereo triangulation\footnote{In structured-light based depth sensors, the quantization error originates from the discrete nature of the disparity map used to extract the depth: this error is commonly mitigated by means of sub-pixel stereo matching algorithms, unfortunately these algorithms require to access low-level data that is usually not accessible from the user side.}, and the misalignment between the pattern projector and the camera. In the case of ToF cameras, there are different sources of errors that contribute to the distortion error, among others the built-in pixel-related errors and the amplitude-related errors, while the global error arise from the so called wiggling error that appears due to irregularities in the internal modulation process\footnote{In structured-light based depth sensors, the quantization error originates from the discrete nature of the disparity map used to extract the depth: this error is commonly mitigated by means of sub-pixel stereo matching algorithms, unfortunately these algorithms require to access low-level data that is usually not accessible from the user side.}. Our method does not directly address other ToF related sources of errors, such as multipath interference and reflectivity related deviations.

In order to analyze the distortion error trend, we compared the measured point clouds with the planes that best fit to them (some results are reported in Fig. 3a, where we used three SL sensors and one ToF sensor). In particular, for each incoming point cloud, we computed the Root Mean Square (RMS) error on the (signed) distance between the plane and the points. It can be noticed that for all the tested sensors, such error is super-linear with respect to the measured depth values, despite the sources of error are different. It is also important to note the different error trends between two sensors of the same type (Kinect1A and Kinect1B): this is a further evidence that an effective calibration is an essential requirement for such sensors. In Fig. 3a we reported the global error of the tested sensors for increasing distances, i.e. the difference between the average depth of the acquired clouds and the ground truth. It can be noticed that in the case of SL sensors, such error is super-linear with respect to the measured depth values, while in the case of a ToF sensor\footnote{Continuous-wave based ToF sensors like the Kinect 2 measure the depth by means of a phase differences between an emitted sinusoidal light wave signal and the backscattered signals received. This phase is evaluated in closed-form using four equally spaced signals\footnote{In structured-light based depth sensors, the quantization error originates from the discrete nature of the disparity map used to extract the depth: this error is commonly mitigated by means of sub-pixel stereo matching algorithms, unfortunately these algorithms require to access low-level data that is usually not accessible from the user side.}.\footnote{The global error trend for the Kinect 2 sensor is plotted also in Fig. 22, where a more suitable scale has been used.} this error has a wiggling
trend, confirming the results of other comprehensive ToF error analysis [8], [44]  

A. Error Correction Model  

To model the effects of the errors introduced by depth sensors, as in [25], [29], [30], [32], we propose to estimate a depth correction function in a per-pixel basis. That is, given a depth sensor $D$ that provides a depth image $I_D$ of size $H_D \times W_D$, a pixel $(u, v)^T$ and the corresponding depth value $z = I_D(u, v)$, the real depth $z^*$ is computed as:

$$ z^* = f_{u,v}(z). \quad (1) $$

$z$ represents both the depth measured by the sensor and the $z$-coordinate of the corresponding 3D point perceived by the depth camera, in a reference system with the $z$ axis corresponding to the optical axis of the camera. 

Starting from the considerations made above, we express each $f_{u,v}(\cdot)$ in (1) as a composition of two functions: $u_{u,v}(\cdot)$ that takes into account the local distortion 1), and $g_{u,v}(\cdot)$ that makes a global correction 2) of the depth values. That is, the real depth $z^*$ is estimated as:

$$ z^* = f_{u,v}(z) = (g \circ u)_{u,v}(z), \quad (2) $$

or, alternatively, given the 3D point $x = (x, y, z)^T$ associated with the pixel $(u, v)^T$, the real 3D point $x^*$ is estimated as:

$$ x^* = \hat{f}_{u,v}(x) = (\hat{g} \circ \hat{u})_{u,v}(x), $$

where

$$ \hat{f}_{u,v}(x) = x \cdot \frac{f_{u,v}(z)}{z}. $$

We define $U$ as the map that associates a pixel $(u, v)^T$ to an undistortion function $u : \mathbb{R} \rightarrow \mathbb{R}$, that is, $U(u, v) = u_{u,v}(\cdot)$. In the same way, we define $G(u, v) = g_{u,v}(\cdot)$ as the map that associates a pixel $(u, v)^T$ to a function of the depth that correct the global error.

IV. CALIBRATION APPROACH

As confirmed by the experimental evidence (see Sect. III), the error on the depth measurements is a smooth function. Thus we can assume that given two close 3D points $x$ and $y$ along the same direction, i.e. $y = (1 + \varepsilon) \cdot x$ with $\varepsilon \simeq 0$,

$$ y^* = \hat{f}(y) = \hat{f}((1 + \varepsilon) \cdot x) \simeq (1 + \varepsilon) \cdot \hat{f}(x) = (1 + \varepsilon) \cdot x^*, $$

where $\hat{f}(\cdot)$ is the error correction function defined in Eq. 2

This means that, if we know how to “correct” a point $x$ (i.e. we know the correction function parameters for this point), we can correct close points with a good approximation using the same parameters.

This assumption is the basis of our algorithm to estimate both the undistortion map $U$ and the global error correction map $G$. Exploiting the fact that both distortion and quantization errors become more severe for increasing distances, we introduce the idea to estimate the distortion error iteratively, starting from short distances and estimating the error for greater distances using as initial guess the current correction parameters.

The proposed calibration framework requires the depth sensor to be coupled with a calibrated RGB camera that frames approximately the same scene: the rigid body transformation that relates the two sensors will be estimated while inferring the depth error correction function. It also requires the two sensors to collect data framing a scene that includes a wall with a checkerboard attached on it, at different distances and orientations.

The calibration is performed in two steps: in the first step the algorithm estimates the undistortion map $U$; only a rough calibration between the camera and the depth sensor is necessary during this step, the checkerboard is used just to have an idea of the wall location. In the second step the global correction map $G$ is computed. Here the checkerboard poses estimated with the (calibrated) RGB camera are used as a ground truth. That is, the undistorted planes estimated in the first step are forced to match the ones defined by the checkerboard. To this end, the real rigid displacement between the RGB camera $C$ and the depth sensor $D$ needs to be known. Unfortunately, to estimate the pose of one sensor with respect to the other, a good estimate of their intrinsic parameters is mandatory. One way to satisfy this circular dependency is to estimate the global correction map $G$ and the rigid body displacement $\hat{C}_lT$ simultaneously.

At this point a question arises: why the depth error is corrected in two steps?

Actually, the reason is simple. To guarantee the best results, the camera-depth sensor transformation $\hat{C}_lT$ and the global correction map $G$ need to be refined together within an optimization framework. Refine inside the same framework a map such as $U$, with a different function every pixel, is not a feasible solution. On the other hand, the map $G$, whose scope is to transform planes into planes, is defined by a dozen parameters (see Sect. VI), thus better suited to be efficiently estimated inside an optimization scheme.
A. Pipeline

The algorithm is organized as in Fig. 4. First of all, the checkerboard corners are extracted from all the collected RGB images $I_{C,k}$ and the organized point clouds $C_k$ are generated from the depth images $I_{D,k}$, $k = 1, 2, \ldots, M$. The corners $I_{C} B_k$ (in pixel coordinates), the point clouds $\{C_k\}$ (in depth sensor reference frame) and the initial camera-depth transformation $\frac{C}{D} T_0$ are the inputs for the undistortion map estimation module. Once the undistortion map $U$ has been estimated, the point clouds are undistorted ($\hat{C}_k$) and passed to the module that estimates both the global correction map $G$ and the final camera-depth transformation $\frac{C}{D} T$.

V. UNDISTORTION MAP ESTIMATION

The proposed algorithm (Fig. 5) estimates the undistortion map $U$ taking as input a list of point clouds $\{D C_1, D C_2, \ldots, D C_M\}$ acquired when the depth sensor $D$ is pointing a planar surface (e.g., a wall) at different distances and orientations. It also requires the positions of the checkerboard corners $\{I C B_1, I C B_2, \ldots, I C B_M\}$, extracted from the images, and a rough estimate of the rigid-body transformation that relates the two sensors $\frac{C}{D} T_0$. The data structure $E_U$ used in Fig. 5 is a matrix of sample sets (one for each sensor pixel) that keeps in memory the samples used to fit the undistortion functions $u_{u,v}(\cdot)$.

Firstly ($\ell \leftrightarrow 1$) the undistortion map $U$ is initialized as an $H_D \times W_D$ matrix of identity functions $1(\cdot) : \mathbb{R} \rightarrow \mathbb{R}$, while the sample matrix $E_U$ is initialized as an $H_D \times W_D$ matrix of empty sets. Then, the point cloud list $\{D C_1, D C_2, \ldots, D C_M\}$ is sorted in ascending order, $\{D C_{s_1}, D C_{s_2}, \ldots, D C_{s_3}\}$, according to the distance of the main plane (i.e., the plane with the checkerboard) from the sensor ($\ell$). 3, to exploit the smoothness described in Sect. IV.

Actually, no plane extraction is performed, the assumption that the RGB camera and the depth sensor are facing the same wall is exploited to sort the point clouds. That is, the checkerboard corners provided in input are used.

The undistortion map is created iteratively: at each step only one point cloud is analyzed ($\ell \leftrightarrow 4$). At step $k$, the $k$-th cloud is undistorted using the current undistortion of $U$ ($\ell \leftrightarrow 5$-$9$). The coordinates $\hat{u}_{s_k} = \{(u, v)^T_{s_k,1}, (u, v)^T_{s_k,2}, \ldots, (u, v)^T_{s_k,n_{s_k}}\}$ of the $s_k$ points that lie to the main plane are extracted from the undistorted cloud (Fig. 11) as described in Sect. IV-A. A plane $D \pi_{s_k}$ is then fitted to the initial cloud $D C_{s_k}$ (Fig. 12) by using only the points selected in $\ell \leftrightarrow 11$. Actually, to increase stability, instead of fitting a plane to the whole original point cloud, only the pixels within a defined ray from the plane center are used, as reported in [32]. Finally, the estimated plane $D \pi_{s_k}$ is used to update the undistortion map $U$ ($\ell \leftrightarrow 13$) as described in Sect. IV-B. The procedure ends as soon as the last cloud in the list has been processed.

A. Wall Points Selection

The selection of the wall point-coordinates $\hat{u}_{s_k}$ is performed automatically, as opposed to the manual selection of [25]. We take advantage of the RGB camera and the checkerboard to select the right plane and extract the coordinates from the undistorted cloud with a RANSAC-based approach [35], [36]. As the example shown in Fig. 6, the undistorted cloud lets us extract the correct points, where the original one does not. In particular, points near the image corners are likely to be excluded from the inliers when using the original cloud.

B. Map Update

In the map update function (Fig. 7), all the points $D x = (x, y, z)^T$ of the cloud that lie to the main plane are projected on the previously extracted plane $D \pi_{s_k}$ along their line-of-sight ($\ell \leftrightarrow 3$-$4$, where $LOS\_PROJECT()$ is a short name for the function $\_LINE\_OF\_SIGHT\_PROJECT()$). That is, let $n^T x - d_n = 0$ be the plane equation, with $n$ the plane unit normal vector and $d_n$ the distance of the plane from the origin, and let $l^D x$,
Fig. 7. Pseudocode of the algorithm for updating the undistortion map $U$.

We estimate the undistortion function $u_{u,v}(\cdot)$ only for the pixels in $S_U$. For all the others, instead, this function is computed as a linear combination of the functions computed for the pixels set $S_U$. That is, given a pixel $(u, v)^T$, following a bilinear interpolation approach, its undistortion function $U(u, v)$ can be computed as:

$$U(u, v) = \sum_{(s, t) \in S_U(u,v)} w_{\chi_U}(u, s) \cdot w_{\psi_U}(v, t) \cdot U(s, t)$$

where

$$w_{\chi_U}(u, s) = 1 - \frac{|u - s|}{\chi_U}, \quad w_{\psi_U}(v, t) = 1 - \frac{|v - t|}{\psi_U}$$

and

$$\sum_{(s, t) \in S_U(u,v)} w_{\chi_U}(u, s) \cdot w_{\psi_U}(v, t) = 1.$$

2) Curve Fitting: As shown in Sect. III (Fig. 5c), the distortion is super-linear, therefore an appropriate correction function must be chosen. Moreover, as previously described, since we are not estimating a function for every pixel, the fitting procedure is not straightforward.

For what concerns the former point, suppose the error is corrected by a second degree polynomial, that is, $U(u, v) = u_{u,v}(z) = a + bz + cz^2$, for some $a, b, c \in \mathbb{R}$. To estimate the polynomial coefficients we solve a non-linear least squares problem of the form:

$$\arg \min_{a,b,c} \sum_{(z, z_{\pi}) \in E_U(u,v)} \frac{1}{\sigma^2(z)} \left\| a + bz + cz^2 - z_{\pi} \right\|^2$$

where $\sigma(z)$ is a normalization term, that is, the error on the depth measurements. For the Kinect 1 we choose $\sigma(z)$ to be the quantization error (as reported in [20]), i.e.

$$\sigma(z) = -0.00029 + 0.00037 \cdot z + 0.001365 \cdot z^2.$$

Fig. 9. Pseudocode of the algorithm for updating the undistortion map \(U\) taking into account the pixel binning.

For Kinects 2, since we didn’t find any suitable equation in the literature, we fitted a second degree polynomial to the samples reported in \cite{3a} i.e.

\[
\sigma(z) = 0.00313 + 0.00116 \cdot z + 0.00052 \cdot z^2.
\]

For what concerns the latter point, i.e, how to deal with the discretized undistortion map, we slightly modify the sample set generation and the function fitting procedure described in Fig. 7. In the new algorithm (Fig. 9), every pixel \( (u, v)^T \) contributes to the sample set of its four surrounding pixels \( S_U(u, v) \) with a weight calculated as in \cite{3}. That is, let:

\[
S_U^{-1}(s, t) \triangleq \{(u, v)^T \in \mathcal{I}_D : (s, t) \in S_U(u, v)\}
\]

be the set of pixels which have \( (s, t) \) as one of their surrounding pixels. For each cloud, the temporary sample set \( E_w (s, t) \) for a pixel \( (s, t) \in S_U \) is (\ell. 2-10):

\[
E_w (s, t) \triangleq \bigcup_{(u, v)^T \in S_U^{-1}(s, t)} \{(w, z, \bar{z})\}
\]

where

\[
w \triangleq w_{\chi} (u, s) \cdot w_{\psi} (v, t).
\]

\( E_w (s, t) \) is used to generate the sample set for the aforementioned curve fitting procedure (\ell. 11-15). Basically, the pair \( (\bar{z}, \bar{z}_\pi) \) is calculated as the weighted arithmetic mean of the values in \( E_w (s, t) \), that is:

\[
W \triangleq \sum_{(w, z, \bar{z}) \in E_w (u, v)} w,
\]

\[
\bar{z} \triangleq \frac{1}{W} \sum_{(w, z, \bar{z}) \in E_w (u, v)} w \cdot z,
\]

\[
\bar{z}_\pi \triangleq \frac{1}{W} \sum_{(w, z, \bar{z}) \in E_w (u, v)} w \cdot z_\pi,
\]

and added to the sample set \( E_U (s, t) \).

VI. GLOBAL CORRECTION MAP ESTIMATION

Our original solution to deal with the global, systematic error was to have a unique function, say \( g(\cdot) \), to correct the wrong depth measurements after the undistortion phase, i.e. \( G(u, v) = g(\cdot) \), for all \( (u, v)^T \in \mathcal{I}_D \). Unfortunately, this solution had one important limitation: in some cases the distorted clouds were both translated and rotated around a non-predictable axis. For this reason we moved to a correction map \( G \) someway similar to the previously described undistortion map \( U \). The actual implementation of such map is described in Sect. VI-C. Our algorithm takes as input a set of already undistorted point clouds \( \{D_{C1}, D_{C2}, \ldots, D_{CM}\} \), the correspondent wall point coordinates \( \{I_1, I_2, \ldots, I_M\} \) and the checkerboard corners extracted from the RGB images, \( \{I_{c1} B_1, I_{c2} B_2, \ldots, I_{cM} B_M\} \). After an initialization step where a rough estimate of the map \( G \) is computed (Sect. VI-A), the map is refined, along with the camera-depth sensor transformation \( \mathcal{P}_{\mathcal{T}} \), within a non-linear optimization framework (Sect. VI-B).

A. Initial Estimation

The algorithm used for the initial estimation of the map functions as well as the computation of the rigid transform between the RGB and the depth sensor is reported in Fig. 10. Firstly, the pose of one sensor with respect to the other is estimated, that is, for each color-depth image pair both the plane defined by the checkerboard in the image \( c \pi_B \) (in the RGB camera \( C \) reference frame), and the one extracted from the point cloud \( \mathcal{P}_{\mathcal{C}k} \) (in the depth sensor \( D \) reference frame) are computed from the given input data (\ell. 1-6). The transformation between the checkerboard and the RGB camera \( (g_{B_C}, \mathcal{P}) \) is estimated given the checkerboard 3D points \( \mathcal{B} \), their corresponding image projections \( \mathcal{I}_{c1} \mathcal{B}_1, \mathcal{I}_{c2} \mathcal{B}_2, \ldots, \mathcal{I}_{cM} \mathcal{B}_M \) and the distortion coefficients \( \text{dist}_{c} \) using an iterative optimization based on the Levenberg-Marquardt method (OpenCV function \text{solvePNP}, \ell. 2, that solves a Perspective-n-Point problem) The checkerboard 3D points are then transformed in the RGB camera frame (\ell. 3). The equation of the plane framed by the RGB camera is hence computed taking 3 non-collinear corners (\ell. 4). The equation of the plane in the depth image, instead, is computed using a SVD approach (\ell. 5). Once all the planes have been computed, the rigid displacement between the two sensors is estimated (\ell. 7-9) using the plane-to-plane calibration method described in \cite{38}.

The plane equations extracted from the images are then represented w.r.t. the depth sensor reference frames using the transformation matrices just computed. These planes are used as reference locations for the curve fitting procedure (\ell. 10-13), as we did with the undistortion map \( U \) in Fig. 5.

B. Non-linear Refinement

Once the global correction map \( G \) and the camera-depth sensor transformation matrix \( \mathcal{P}_{\mathcal{T}} \) have been estimated, we refine them within a non-linear optimization framework. To take into account the error on the checkerboard poses estimation, we follow the bundle-adjustment approach as described
Input: \{P \hat{C}_1, P \hat{C}_2, \ldots, P \hat{C}_M\} \rightarrow \text{Undistorted point clouds}
Input: \{I_1, I_2, \ldots, I_M\} \rightarrow \text{Wall point coordinates}
Input: \{c B_1, c B_2, \ldots, c B_M\} \rightarrow \text{Checkerboard corners}
Output: G \rightarrow \text{Global error correction map}
Output: \hat{\mathbf{C}} \rightarrow \text{Camera-depth sensor transformation matrix}

1: for \(k \leftarrow 1, 2, \ldots, M\) do
2: \(\hat{c} B_k \leftarrow \text{solvePNP}(K_c, \text{dist}_{c}, \hat{B} B_k)\)
3: \(\hat{c} B_k \leftarrow \hat{c} B_k \cdot \hat{B}\)
4: \(\hat{\pi} B_k \leftarrow \text{fitPlane}(\hat{c} B_k)\)
5: \(\hat{\pi} B_k \leftarrow \hat{\pi} B_k \cdot \hat{B}\)
6: end for
7: \(\Pi_B \leftarrow (\hat{\pi} B_1, \hat{\pi} B_2, \ldots, \hat{\pi} B_M)\)
8: \(\Pi_G \leftarrow (\hat{\pi} C_1, \hat{\pi} C_2, \ldots, \hat{\pi} C_M)\)
9: \(\hat{\mathbf{C}} \leftarrow \text{estimateTransform}(\Pi_B, \Pi_G)\)
10: for \(k \leftarrow 1, 2, \ldots, M\) do
11: \(\hat{\pi} B_k \leftarrow \hat{\mathbf{C}} \cdot \hat{\pi} B_k\)
12: \((G, E) \leftarrow \text{updateMap}(G, E, \hat{\pi} C_k, I_k, \hat{\pi} B_k)\)
13: end for

Fig. 10. Pseudocode of the algorithm for the initial estimation of the global correction map \(G\).

in [39]: we also refine all the checkerboard poses \(c B_k\), with \(k = 1, \ldots, M\). Moreover, to take into account the error on the intrinsic parameters of the depth camera \(K_D\), the focal lengths and the principal point are refined too. So, let define \(C T_B \triangleq \{c B_1, c B_2, \ldots, c B_M\}\) as the set of checkerboard poses in the camera coordinates, estimated with the \text{solvePNP} function.

Formally, the results of the non-linear refinement is:

\[
(G, c \mathbf{T}, C T_B, K_D) = \arg \min_{G, c \mathbf{T}, C T_B, K_D} \sum_{k=1}^{M} e_{\text{repr}}(k) + e_{\text{pos}}(k)
\]

Here \(e_{\text{repr}}\) takes into account the reprojection error of the checkerboard corners onto the images and depends on the checkerboard poses only. This error component is defined as:

\[
e_{\text{repr}}(k) \triangleq \sum_{(r,c) \in B_k} \frac{1}{\sigma_C} \left\| \text{proj}_C (c \mathbf{B}_k \cdot B_k(r,c)) - \pi\mathbf{B}_k(r,c) \right\|^2
\]

The summation is performed over all the checkerboard corners, \(\text{proj}_C\) is a general projection function that depends on both the camera matrix \(K_C\) and the distortion coefficients \(\text{dist}_C\). The residuals are weighted by the inverse of the variance of the corner estimation error \(\sigma_C^2\), where \(\sigma_C = 0.2\).

\(e_{\text{pos}}\) represents the error between the planes defined by the checkerboards and the ones defined by the undistorted point cloud

\[
e_{\text{pos}}(k) \triangleq \sum_{(u,v) \in I_k} \frac{1}{\left\| I_k \cdot \sigma_T^2 \right\|} \left\| \text{proj}_{\pi_k} (g_{u,v} (D \hat{C}_k(u,v))) - g_{u,v} (D \hat{C}_k(u,v)) \right\|^2
\]

where \(\text{proj}_{\pi_k}(x)\) is the function that orthogonally projects a point \(x\) onto plane \(\pi\). Formally speaking, this error is the distance between the cloud point \(D \hat{C}_k(u,v)\) corrected with the current estimation of \(G\) and its line-of-sight projection onto the plane \(D \pi_k\) defined by the checkerboard corner set \(D B_k\). Such set is computed as

\[
D B_k = D \hat{C}_k \cdot c B_k \cdot B
\]

Finally, each residual is weighted by the inverse of the variance on the depth measurements after the undistortion phase \(\sigma_T^2(z)\), multiplied by the number of wall points, i.e. \(\left\| I_k \right\|\).

C. Implementation Details

1) Global Correction Map: As mentioned before, the global correction map \(G\) is someway similar to the undistortion map \(U\), but more simple. In fact, \(G\) needs to transform planes into planes and, recalling that a plane transformation has 3 degrees of freedom, we just need 3 functions to satisfy this requirement. Thus we define \(G\) as a discretized map constructed as \(U\) with \(\chi_G = W_D\) and \(\psi_G = H_D\), that is, only 4 pixels contain a correction function \(g_{u,v}(\cdot)\). For what concerns the other pixels, the global correction function is computed as a linear combination of the functions of the 4 boundary pixels. Allowing 4 pixels to control the whole map usually leads to wrong results. Let suppose, for example that 3 of such pixels contain an identity function and the fourth does not. Clearly the resulting surface will not be a plane anymore. For this reason, only 3 of these pixels are actually computed, the fourth is instead estimated exploiting the following invariant:

\[
\frac{g_{0,0}(z) + g_{W_D, H_D}(z)}{2} = \frac{g_{W_D, 0}(z) + g_{0, H_D}(z)}{2}
\]

Suppose now that \(g_{W_D, H_D}(\cdot)\) is the dependent function:
\(g_{W_D, H_D}(\cdot)\) can be estimated by fitting a function on an adequate set of pairs \((d, g_{W_D, H_D}(d))\), where

\[
g_{W_D, H_D}(z) = g_{W_D, 0}(z) + g_{0, H_D}(z) - g_{0, 0}(z)
\]

is computed from [1]. An example of the presented global correction map \(G\) is reported in Fig. [11].

2) Curve Fitting: Since the correction map \(G\) is constructed in the same way as the undistortion map \(U\), the considerations on the curve fitting procedure made in Sect. V-C2 are still valid in the global error case.

Fig. 11. Visualization of a global correction map \(G\). A global correction function is estimated for all and only the pixels in \(S_G\). For all the others pixels, instead, the function is computed as a linear combination of the ones estimated for the pixels in \(S_G\).
device two datasets: a training set meters, and a high resolution RGB camera (see Fig. 12a). support that includes two rigidly mounted high precision laser systems. Each sensor has been mounted, one at a time, on a camera calibration is an essential requirement of all the tested approaches. Actually, a good RGB camera of each device has been previously calibrated with a standard calibration tool. We used four RGB-D sensors: two Microsoft Kinect 1 (called KINECT1A and KINECT1B in the plots), an Asus Xtion Pro Live (called ASUS in the plots), and a Microsoft Kinect 2. The RGB camera of each device has been previously calibrated exploiting a standard calibration tool. Actually, a good RGB camera calibration is an essential requirement of all the tested systems. Each sensor has been mounted, one at a time, on a support that includes two rigidly mounted high precision laser distance meters.

We attached a checkerboard on a wall, collecting for each device two datasets: a training set (i.e., the dataset used to perform the calibration) and a test set (i.e., the dataset used to evaluate the calibration accuracy). The training set contains views of the checkerboard from the device camera, the depth sensor and the high resolution camera from different locations and orientations. The test set, instead, has been acquired by positioning the support of Fig. 12a orthogonal to the wall at different distances and measuring such distances with the two laser distance meters.

We independently analyze the results of our undistortion approach (Sect. VII-A), the results of our global correction approach (Sect. VII-B), and the provided camera-depth sensor transformation accuracy (Sect. VII-C). We also compare our method with other state-of-the-art calibration systems (Sect. VII-D), using the original implementations provided by the authors and a reference pattern as a ground truth (Fig. 12b). In almost all tests, our system outperforms the other evaluated systems. We finally report some experiments of an RGB-D visual odometry system applied to a mobile robot, where we show that our method is able to provide robust and state-of-the-art results.

VII. EXPERIMENTAL EVALUATION

The goal of the presented experimental evaluations is to show that our method is able to provide robust and state-of-the-art calibration results for different types of RGB-D sensors. We used four RGB-D sensors: two Microsoft Kinect 1 (called KINECT1A and KINECT1B in the plots), an Asus Xtion Pro Live (called ASUS in the plots), and a Microsoft Kinect 2. The RGB camera of each device has been previously calibrated exploiting a standard calibration tool. Actually, a good RGB camera calibration is an essential requirement of all the tested systems. Each sensor has been mounted, one at a time, on a support that includes two rigidly mounted high precision laser distance meters, and a high resolution RGB camera (see Fig. 12a).

We attached a checkerboard on a wall, collecting for each device two datasets: a training set (i.e., the dataset used to perform the calibration) and a test set (i.e., the dataset used to evaluate the calibration accuracy). The training set contains views of the checkerboard from the device camera, the depth sensor and the high resolution camera from different locations and orientations. The test set, instead, has been acquired by positioning the support of Fig. 12a orthogonal to the wall at different distances and measuring such distances with the two laser distance meters.

We independently analyze the results of our undistortion approach (Sect. VII-A), the results of our global correction approach (Sect. VII-B), and the provided camera-depth sensor transformation accuracy (Sect. VII-C). We also compare our method with other state-of-the-art calibration systems (Sect. VII-D), using the original implementations provided by the authors and a reference pattern as a ground truth (Fig. 12b). In almost all tests, our system outperforms the other evaluated systems. We finally report some experiments of an RGB-D visual odometry system applied to a mobile robot, where we show that our method is able to provide robust and state-of-the-art results.

We attached a checkerboard on a wall, collecting for each device two datasets: a training set (i.e., the dataset used to perform the calibration) and a test set (i.e., the dataset used to evaluate the calibration accuracy). The training set contains views of the checkerboard from the device camera, the depth sensor and the high resolution camera from different locations and orientations. The test set, instead, has been acquired by positioning the support of Fig. 12a orthogonal to the wall at different distances and measuring such distances with the two laser distance meters.

We independently analyze the results of our undistortion approach (Sect. VII-A), the results of our global correction approach (Sect. VII-B), and the provided camera-depth sensor transformation accuracy (Sect. VII-C). We also compare our method with other state-of-the-art calibration systems (Sect. VII-D), using the original implementations provided by the authors and a reference pattern as a ground truth (Fig. 12b). In almost all tests, our system outperforms the other evaluated systems. We finally report some experiments of an RGB-D visual odometry system applied to a mobile robot, where we show that our method is able to provide robust and state-of-the-art results.

We attached a checkerboard on a wall, collecting for each device two datasets: a training set (i.e., the dataset used to perform the calibration) and a test set (i.e., the dataset used to evaluate the calibration accuracy). The training set contains views of the checkerboard from the device camera, the depth sensor and the high resolution camera from different locations and orientations. The test set, instead, has been acquired by positioning the support of Fig. 12a orthogonal to the wall at different distances and measuring such distances with the two laser distance meters.

We independently analyze the results of our undistortion approach (Sect. VII-A), the results of our global correction approach (Sect. VII-B), and the provided camera-depth sensor transformation accuracy (Sect. VII-C). We also compare our method with other state-of-the-art calibration systems (Sect. VII-D), using the original implementations provided by the authors and a reference pattern as a ground truth (Fig. 12b). In almost all tests, our system outperforms the other evaluated systems. We finally report some experiments of an RGB-D visual odometry system applied to a mobile robot, where we show that our method is able to provide robust and state-of-the-art results.

We attached a checkerboard on a wall, collecting for each device two datasets: a training set (i.e., the dataset used to perform the calibration) and a test set (i.e., the dataset used to evaluate the calibration accuracy). The training set contains views of the checkerboard from the device camera, the depth sensor and the high resolution camera from different locations and orientations. The test set, instead, has been acquired by positioning the support of Fig. 12a orthogonal to the wall at different distances and measuring such distances with the two laser distance meters.

We independently analyze the results of our undistortion approach (Sect. VII-A), the results of our global correction approach (Sect. VII-B), and the provided camera-depth sensor transformation accuracy (Sect. VII-C). We also compare our method with other state-of-the-art calibration systems (Sect. VII-D), using the original implementations provided by the authors and a reference pattern as a ground truth (Fig. 12b). In almost all tests, our system outperforms the other evaluated systems. We finally report some experiments of an RGB-D visual odometry system applied to a mobile robot, where we show that our method is able to provide robust and state-of-the-art results.

We attached a checkerboard on a wall, collecting for each device two datasets: a training set (i.e., the dataset used to perform the calibration) and a test set (i.e., the dataset used to evaluate the calibration accuracy). The training set contains views of the checkerboard from the device camera, the depth sensor and the high resolution camera from different locations and orientations. The test set, instead, has been acquired by positioning the support of Fig. 12a orthogonal to the wall at different distances and measuring such distances with the two laser distance meters.

We independently analyze the results of our undistortion approach (Sect. VII-A), the results of our global correction approach (Sect. VII-B), and the provided camera-depth sensor transformation accuracy (Sect. VII-C). We also compare our method with other state-of-the-art calibration systems (Sect. VII-D), using the original implementations provided by the authors and a reference pattern as a ground truth (Fig. 12b). In almost all tests, our system outperforms the other evaluated systems. We finally report some experiments of an RGB-D visual odometry system applied to a mobile robot, where we show that our method is able to provide robust and state-of-the-art results.
error increase starts being non-negligible.

In our experience, we found that a bin size of $4 \times 4$ pixels represents a good trade-off between computational efficiency and robustness. Actually, as mentioned before, larger bins tend to fail close to the image corners, while in other experiments we noticed that smaller bins tend to perform badly with small calibration datasets because of the lack of data for some pixels.

3) Test Set Results: We finally tested our algorithm against the test sets. Results of the planarity error evaluation are reported in Fig. 17. As expected, for the three SL sensors the proposed method permits to drastically improve the planarity of the depth data generated by the calibrated sensor. Looking at the plots one could argue: why isn’t the error after the undistortion closer to zero? Actually, to the best of our knowledge, the error curve calculated after the undistortion is mainly due to the sensor noise and the quantization error. Therefore it is not possible to further reduce this error. The error reduction is instead less substantial in the case of kinect 2, especially for increasing distances. Actually, for increasing distances, large areas of the image near the borders just provide random depth values: most of the remaining error in Fig. 17 is due to this unpredictable white noise.

In Fig. 18 the undistortion maps estimated using a bin size of $4 \times 4$ pixels are shown. Looking at the scales, we can see that the magnitude of the correction is consistent with the planarity error of the original data. In the Kinect 2 case, for increasing distances the polynomials close to the borders tend to diverge: this is due to the fact that they are trying to correct just white noise. In Fig. 19 the results of our undistortion algorithm applied to the clouds of Fig. 1 are reported. As expected, the clouds are now planar but they are not in the right position, not even correctly oriented. These errors will be corrected in the next stage of our algorithm.

B. Global Correction Map

In this section we report some results of the evaluation of the estimated global correction map $G$. Recalling that $G$ is computed using the checkerboard as the reference plane and that $G$ and the RGB camera-depth sensor transformation are refined together, also the estimated transformation is taken into account to evaluate the results. We estimate the error of the plane that results after the global correction with respect to the plane defined by the checkerboard.

Firstly, the pose of the checkerboard with respect to the camera is estimated using the corners extracted from the image. Then, the checkerboard plane is transformed into depth sensor coordinates. Finally, the average distance of the wall points (extracted from the cloud) to the checkerboard-defined plane is computed.

1) Global Correction Map Functions: Before evaluating the global correction map $G$, as we did for the undistortion map $U$, we analyze the sample sets generated to compute the map to evince the most appropriate function type to fit to the data. A first analysis of the error has been reported in Sect. III in Fig. 3b. Such error was computed by evaluating the difference between the average depth of a distorted point cloud and the measurements provided by a laser distance meter. Our sample sets, instead, contain pairs $(\tilde{z}, z_{\pi B})$, where

![Fig. 14. Planarity error of the wall points when changing the bin size. In the plot it is visible that increasing the bin size also the error increases, but not as much as expected. Actually, only with bin sizes staring from $16 \times 16$ the error increase starts being non-negligible.](image1)

![Fig. 15. Top-view of the cloud of a planar surface undistorted using maps with different bin sizes. Note that the resulting clouds are similar, especially the four on the left (points with different y-coordinates are drawn with different colors).](image2)

![Fig. 16. Undistortion maps computed using different bin size, evaluated at a distance of 3 meters.](image3)
Fig. 17. Planarity error for the four sensors. For the SL sensors, the proposed approach is able to drastically reduce the distance of the measured points from the plane that best fits the data. Here, the error after the undistortion phase is mainly due to quantization [30]. For the Kinect 2 sensor, instead, the difference is bounded by the random noise that appears with increasing distances.

(a) Planarity error for the three SL sensors.

(b) Planarity error for the Kinect 2 sensor.

Fig. 18. Maps generated by the algorithm for the four sensors with a bin size of 4 x 4 pixels. For each sensor the evaluation of the respective map at 1, 2, 3, and 4 meters is reported. Note that each map has its own scale and all values are in meters.

Fig. 19. Top and side views of the point clouds of Fig. 17 after the undistortion phase. Again, the gray lines show the depth measured by means of the laser meters, while points with different y-coordinates are drawn with different colors. As we can see, the clouds are now more planar than the original ones, however, they are not in the right position, not even correctly oriented.

\[ \hat{z} \] is the depth value after the undistortion phase, and \( z_{\pi_B} \) is the expected depth, i.e. the depth of the pixel as if it were laying on checkerboard-defined plane \( \pi_B \). Even in this case we tried to fit polynomial functions with different degrees: in Fig. 20 we report a comparison between quadratic and linear functions for two of the four sample sets used to generate the global correction map (we used in this case a SL sensor). From the figure, it is clear that linear functions are not suitable since they do not fit properly to the data. A further confirmation of this fact is visible in Fig. 21 where the results of the calibration process varying the maximum degree of the polynomials from 1 to 4 is reported. All the calibrations of the SL sensors reported in the following were performed treating each \( g_{u,v}(\cdot) \) as a quadratic function with the constant factor set to zero. We repeated such tests also for the ToF camera, in this case testing a 3-degree and a 6-degree polynomial, that are functions suitable to model the wiggling error, as reported by [8]. We reported the better results using the 6-degree polynomial with non zero constant factor: all the calibrations of the ToF sensor reported in the following were performed using this function.

2) Test Set Results: We finally estimated the global correction results on the acquired test sets. For each test cloud we evaluated the distances of the points of the main plane to the plane defined by the checkerboard and computed their mean. The plots in Fig. 22 show the results of such evaluation. The proposed error correction approach is working as expected: all the points are correctly translated to the right location, with respect to the checkerboard pose.
Fig. 20. Analysis of two of the sample sets used to estimate the global correction map $G$. The sample set is composed by pairs $(x, y) = (\hat{z}, z_B)$, where $\hat{z}$ is the sensor-provided depth while $z_B$ is the depth defined by the checkerboard $B$ attached on the wall. The plots at the top show the samples as well as a linear and a quadratic function that best approximate them. The plots in the middle, instead, show the difference between the samples’ $y$ and $x$ values, i.e. $z_B - \hat{z}$. Finally, in the bottom plots, the residuals for the two functions are reported.

Fig. 21. Global error when varying the maximum degree of the global correction polynomials. From the plot we can see that linear functions are not able to model (and correct) the error on the average depth estimation.

C. Testing the Whole Procedure

The following tests are meant to evaluate the results of the proposed calibration approach when dealing with real world data. To this aim, we first compare the wall average depths obtained after the calibration with the measurements given by the laser meters, then the transformations between the depth sensors and the cameras are evaluated in terms of visual results and expected values.

1) Depth Calibration: The plots in Fig. 23 show a quantitative evaluation of the depth error, i.e. the distance between the wall measured by means of the laser meters and the average depth of the points after both the undistortion and global correction phases. The measured planes are within a couple of centimeters from the real ones: these good results confirm the soundness of our choices.

We also evaluated how much the resulting plane is rotated with respect to the real one. To this aim we computed the angle between the normal of the plane fitted to the corrected data, and the $x$- and $y$-axis of the wall plane, i.e. $(1, 0, 0)^T$ and $(0, 1, 0)^T$ respectively. Let $\mathbf{n}$ be the fitted-plane normal and let $\mathbf{a}$ be the axis with respect to which the error is computed, the rotation error, $\varepsilon_{\text{rot}}$, is

$$\varepsilon_{\text{rot}} = \arccos(\mathbf{n}^T \mathbf{a}) - \frac{\pi}{2}.$$ 

Results of the error computation for sensor KINECT1B are reported in Fig. 24. The figure shows that the rotation about the $x$-axis is completely corrected. For what concerns the rotation about the $y$-axis, instead, the results are worse. The reason for
Fig. 23. Distance between the real wall depth and the one estimated with the calibration procedure. The error is computed for the original point clouds (Original) and for the clouds after both the undistortion and the global error correction (Corrected). Moreover, the distance of the wall from the color sensor estimated using the checkerboard (Checkerboard) is reported. For the Kinect 1 sensors, the error is computed using (a) the device camera as the reference camera as well as (b) the external high resolution one. Note that there is a fixed offset of about than 1 cm between the laser meters and the two Kinect 1 and the Kinect 2 sensors (the sensors are closer to the wall) and about 9 cm between the laser meters and the high resolution camera (the camera is farther).

Fig. 24. Rotation error for Kinect1B sensor. Both the rotation about the x- and y-axis are compared. The error is the angle estimated between the normal of the plane fitted to the corrected data and the theoretical wall plane x-axis and y-axis.

Fig. 25. Top and side views of the point clouds of Fig. 1 after the undistortion phase (Fig. 19) and the global correction phase. Again, the gray lines show the depth measured by means of the laser meters. As we can see, every cloud is now planar as well as in the right position and correctly oriented.

2) Camera-Depth Sensor Transform: Even if the camera-to-depth sensor transform $T_C^{D}$ estimated during the optimization phase is a sort of “side effect” of the depth calibration, a good transformation can be seen as a proof of the validity of the proposed approach. In Tab. I and Tab. II the transformations that resulted from the calibration of the sensors using their device cameras, are reported. Moreover, to give a comparison metric, also the factory-provided transformation is reported. The values obtained are similar to those obtainable with other state-of-the-art calibration tools for RGB-D devices [25], [40], [26], [22].

D. Performance Comparison

We tested the calibration accuracy of our system against two state-of-the-art calibration methods, the one from Herrera et al. [25] and the one from Staranowicz et al. [26], using the original implementations provided by the authors. Thanks to its robustness and accuracy, [25] is often used as a benchmarking method to calibrate RGB-D pairs; [26] is a more recent method that, compared to [25] and our method, employs a novel, alternative calibration procedure based on a spherical pattern. We used two different types of RGB-D
TABLE I
Camera-depth sensor transform estimated for the three SL sensors when calibrated using the device camera. Both the translation $t = (t_x, t_y, t_z)^T$ and the rotation, represented as a quaternion $q = (q_w, q_x, q_y, q_z)^T$, are reported. The factory line contains the factory-provided calibration parameters.

Fig. 26. Accuracy in the reference cube localization for increasing depths.

sensors: a Kinect 1 and a Kinect 2. For each method, we acquired large training sets, framing the calibration pattern (a wall for [25] and our method, a basket ball for [26]) from several positions. In order to compare the calibration accuracy, we collected a test set framing a big reference hollow cube with large checkerboards attached to each visible side (Fig. 12b). The three checkerboards allow us to compute the plane equations of the three cube sides even if they are not orthogonal to each other. We use these planes, their intersection point $x_c$ and its projection in the image plane $\text{proj}_C(x_c)$ as ground truth data. For each tested method, we estimated the plane equations by fitting the three planes to the (corrected) point clouds, computing also their intersection point $x'_c$ as well as its projection in the image plane $\text{proj}_C(x'_c)$. In our performance comparison, we report the average $\mu(\cdot)$ and standard deviation $\sigma(\cdot)$ of both the errors $\varepsilon_3 = \|x_c - x'_c\|$ and $\varepsilon_2 = \|\text{proj}_C(x_c) - \text{proj}_C(x'_c)\|$, computed for all the images included in the test set. We also report the average of the angular deviations $\angle_x, \angle_y, \angle_z$ between the ground truth planes and the estimated planes. For a perfect calibration, these errors should be obviously 0.

Table III shows the performance comparison results of the three tested method for a Kinect 1 sensor; as baseline, we also report the results obtained using the original, factory-calibrated data. Fig. 26 shows error $\varepsilon_3$ for increasing depths from the reference cube. Our method clearly provide the better calibration accuracy. The good results obtained by the method from Herrera et al. confirm that the choice of a planar calibration pattern enables to obtain superior calibration results. The poor results obtained by the method from [26] are mainly due to the inaccuracies of the calibration pattern detector: we collected several training sets, framing a basket ball (as suggested by the authors) from a large number of different positions, but the provided ball detector often failed to provide an accurate localization.

We also compared the calibration accuracy of our method
against the factory calibration in the case of a Kinect 2 sensor [Tab. IV]. The method from Herrera et al. is here not applicable since it operates directly on the disparity map provided by a SL sensor: clearly a ToF sensor does not provide such map. Also in this case, our method outperforms the factory calibration, enabling to obtain better data also in the case of a ToF sensor.

E. Visual Odometry Use Case

As a further validation of our method, we present an experiment performed using a real robot running an RGB-D visual odometry system. Here we show how the accuracy in the ego-motion estimation and the 3D reconstruction can highly benefit from using RGB-D data calibrated with our method. We employed two different RGB-D visual odometry systems: the popular and robust DVO (Dense Visual Odometry) [41] and a very simple custom-built system based on dense optical flow, in the following OFVO (Optical Flow Visual Odometry). DVO registers two consecutive RGB-D frames by minimizing the photometric error between corresponding pixels while OFVO firstly computes the dense optical flow between a reference and the current RGB image and, after generating the point cloud of the reference frame using the depth image, it estimates the relative rigid motion motion by solving a Perspective-n-Point problem. These methods strongly rely on both the intrinsic and extrinsic calibration of the RGB-D pair, so they represent a perfect benchmark for our method which provides the complete calibration for such sensors.

We moved a mobile robot (a MobileRobots Pioneer 3-AT) equipped with a Microsoft Kinect 1 along a known trajectory, then we estimated the motion using both DVO and OFVO on the original RGB-D data and on the same data corrected with our method. Table Tab. V shows the root mean square error (RMSE) of the estimated motion for each experiment: in both cases the accuracy improvement is remarkable. Fig. 27(a) shows a top view of the estimated and ground truth trajectories, along with the generated point clouds (Fig. 27(b), (c)). For both methods, the trajectory estimated using the corrected data is clearly closer to the ground truth compared to the one estimated using the original data: in the first case, most of the misalignment is mainly due to a drift accumulated in the first turn, where the robot acquired a sequence of frames with very few visual features. The trajectory estimated using the original data tends to diverge also due to a sort of “scale drift” effect that supports our choice to introduce the global component in our error model. Similarly, the quality and the precision of the reconstructed point cloud highly benefits from using the corrected data.

F. Runtime Performance

The proposed algorithm has been implemented in C++ as a ROS [7] package using the OpenCV [42] library for image processing, the Point Cloud Library (PCL) [35] for 3D data processing, and the Ceres Solver library [43] to solve the optimization problems. To perform the calibration, the user is asked to capture a training set using a tool provided in the package, by moving the sensor in front of a wall with a checkerboard attached on it. Collecting a typical dataset of a hundred images takes no more than 10 minutes.

We tested both the calibration and the correction stages in terms of the execution time. The whole calibration process takes about 45 minutes on a consumer laptop (for 640 × 480 depth images and 5 minutes by downsampling the depth images to a resolution of 320 × 240 pixels: it is worth to mention that in the last case, the calibration accuracy is not significantly reduced. The calibration is an operation that is performed once and so the execution time is not critical. On the other side, the execution time of the correction stage node is critical, since the data generated by the RGB-D sensor, typically with a frequency of 30 Hz, should be processed in real-time. We tested the performance of 3 different implementations of the correction algorithm:

- a standard CPU implementation;
- a parallel CPU implementation exploiting the OpenMP directives;
- a parallel GPU implementation using CUDA.

The results are reported in Table VI. Note that these execution times include the time to generate the point cloud from the depth image too. Clearly the GPU implementation outperforms the CPU ones, but dedicated hardware is needed. Most of the time (about 95%) spent by the GPU implementation is dedicated to the copy of the data to and from the GPU memory. Anyway, all the implementations are able to correct the data in real-time. Also, it is worth to say that the bin size does not affect the performance, since the implementation exploits a lookup-table to store the correction functions.

VIII. Conclusions

In this paper we presented a novel method to calibrate a general RGB-D sensor. The proposed calibration procedure only requires the user to collect data in a minimally structured environment, providing in output both the intrinsic and extrinsic parameters of the sensor. We proposed to generalize

\[^{10}\text{CPU: Intel Core i7-4700MQ, RAM: 16GB, SSD, GPU: NVidia GTX 750M.}\]
the depth sensor error by means of two different components, a distortion error and a global, systematic error. The distortion error is modeled using a per-pixel parametric undistortion map, estimated in the first stage of the algorithm. The depth systematic error along with the camera-depth sensor alignment are estimated in the second stage of the algorithm, inside a robust optimization framework. We reported a comprehensive set of tests that support the introduced model. We finally presented exhaustive experiments performed using several sensors, showing that our approach provides highly accurate results, outperforming other state-of-the-art methods.

Comparing with other methods, our approach is well suited for different types of depth sensors while requiring a relatively easy calibration protocol.

IX. ACKNOWLEDGMENTS

The research work is partially supported by: the European Commission under 601116-ECHORD++ (FlexSight experiment) and the University of Padua under the project DVL-SLAM.

Filippo Basso was born in Italy in 1987. He received the B.Sc., M.Sc., and Ph.D. degrees in Computer Engineering from University of Padua, Padua, Italy, in 2009, 2011, and 2015, respectively. He joined IT+Robotics, Padua, Italy, in 2015, a company active in the field of industrial vision, robotics, and workcell simulation applications, where he is currently a Senior Developer and R&D Manager. His main areas of research interest are 2D/3D computer vision, sensor fusion, and robotics.

Emanuele Menegatti Menegatti is Full Professor of the School of Engineering at Dept. of Information Engineering of University of Padua since 2017. He received his Ph.D. in Computer Science in 2003, in 2005 he became Assistant Professor and Associate Professor in 2010. Menegatti was guest editor of five special issues of the journal Robotics and Autonomous Systems Elsevier. Menegatti’s main research interests are in the field of Robot Perception and 3D distributed perception systems. In particular, he is working on RGB-D people tracking for camera network, neuorobotics and service robotics. He is teaching master courses on Autonomous Robotics, Three-dimensional data processing and bachelor course in Computer Architecture and a course for school teachers on Educational Robotics. He was coordinator of the FP7 FoF-EU project Thermobot and local principal investigator for the European Projects 3DComplete and FibreMap and Focus in FP7; eCraf2Leam and Spirit in H2020. He was general chair of the 13th International Conference “Intelligent Autonomous System” IAS-13 and was program chair of IAS-14 and IAS-15. He is author of more than 50 publications in international journals and more than 120 publications in international conferences. In 2005, Menegatti founded IT+Robotics, a Spin-off company of the Univ. of Padua, active in the field of industrial robot vision, machine vision for quality inspection, automatic off-line robot programming. In 2014, he founded EXiMotion a startup company active in the field of educational robotics and service robotics.

Alberto Pretto Alberto Pretto is Assistant Professor at Sapienza University of Rome since October 2013. He received his Ph.D. degree in October 2009 from the University of Padua, where he worked as a postdoctoral researcher at the Intelligent Autonomous Systems Lab (Department of Information Engineering). Between 2011 and 2012 he spent a 9 months visiting research fellowships at the UCLA VisionLab, Los Angeles (USA). In 2004 and 2005, he has been working as software engineer at Padova Ricerca Scpa. In 2005, he was one of the funders of the B.Sc., M.Sc., and Ph.D. degrees in Computer Engineering at Dept. of Information Engineering of University of Padua. In 2010, he founded IT+Robotics, a spin-off company of the University of Padua working on robotics and machine vision. Alberto Pretto’s main research interests include robotics and computer vision.
