ABSTRACT The molecular mechanisms of alginate polymerization/modification/secretion by a proposed envelope-spanning multiprotein complex are unknown. Here, bacterial two-hybrid assays and pulldown experiments showed that the catalytic subunit Alg8 directly interacts with the proposed copolymerase Alg44 while embedded in the cytoplasmic membrane. Alg44 additionally interacts with the lipoprotein AlgK bridging the periplasmic space. Site-specific mutagenesis of Alg44 showed that protein-protein interactions and stability were independent of conserved amino acid residues R17 and R21, which are involved in c-di-GMP binding, the N-terminal PilZ domain, and the C-terminal 26 amino acids. Site-specific mutagenesis was employed to investigate the c-di-GMP-mediated activation of alginate polymerization by the PilZAlg44 domain and Alg8. Activation was found to be different from the proposed activation mechanism for cellulose synthesis. The interactive role of Alg8, Alg44, AlgG (epimerase), and AlgX (acetyltransferase) on alginate polymerization and modification was studied by using site-specific deletion mutants, inactive variants, and overproduction of subunits. The compositions, molecular masses, and material properties of resulting novel alginates were analyzed. The molecular mass was reduced by epimerization, while it was increased by acetylation. Interestingly, when overproduced, Alg44, AlgG, and the nonepimerizing variant AlgG(D324A) increased the degree of acetylation, while epimerization was enhanced by AlgX and its nonacetylating variant AlgX(S269A). Biofilm architecture analysis showed that acetyl groups promoted cell aggregation while nonacetylated polymannuronate alginate promoted stigmergy. Overall, this study sheds new light on the arrangement of the multiprotein complex involved in alginate production. Furthermore, the activation mechanism and the interplay between polymerization and modification of alginate were elucidated.

IMPORTANCE This study provides new insights into the molecular mechanisms of the synthesis of the unique polysaccharide, alginate, which not only is an important virulence factor of the opportunistic human pathogen Pseudomonas aeruginosa but also has, due to its material properties, many applications in medicine and industry. Unraveling the assembly and composition of the alginate-synthesizing and envelope-spanning multiprotein complex will be of tremendous significance for the scientific community. We identified a protein-protein interaction network inside the multiprotein complex and studied its relevance with respect to alginate polymerization/modification as well as the c-di-GMP-mediated activation mechanism. A relationship between alginate polymerization and modification was shown. Due to the role of alginate in pathogenesis as well as its unique material properties harnessed in numerous applications, results obtained in this study will aid the design and development of inhibitory drugs as well as the commercial bacterial production of tailor-made alginates.

Pseudomonas aeruginosa is an opportunistic human pathogen which can become life-threatening in immunocompromised patients. It is the leading cause of morbidity and mortality in cystic fibrosis patients. This is due mainly to its ability to colonize lungs by forming structured biofilms which consist of bacterial cells embedded in a complex matrix predominantly composed of alginate. Bacterial cells in biofilms are protected against the immune system and antibiotics (1, 2). Alginates are anionic exopolysaccharides composed of variable proportions of 1,4-linked β-D-mannuronic acid (M) and its C-5 epimer α-L-guluronic acid (G). The alginate derived from P. aeruginosa is naturally acetylated and lacks consecutive G residues (GG-blocks) (3). Alginates exhibit unique gel-forming properties suitable for numerous medical and industrial applications (3, 4). The alginate structure strongly impacts its material properties. Hence, the development of bioengineering approaches to control the alginate structure will enable production of alginates with new material properties toward novel applications.

For many years, P. aeruginosa has been the model organism to study various aspects of alginate biosynthesis, such as polymerization, epimerization, acetylation, secretion, and regulation. Thirteen proteins are directly involved in the biosynthesis of alginate,
and except for \textit{algC}, their encoding genes are clustered in the alginate biosynthesis operon \textit{(algD, alg8, alg44, algK, algE, algG, algX, algL, algJ, algF, algA)} (5, 6). Except for soluble cytoplasmic proteins AlgA, AlgC, and AlgD, which are responsible for providing the activated nucleotide sugar precursor, GDP-mannuronic acid, proteins encoded by the operon are proposed to constitute an envelope-spanning multiprotein complex. Two cytoplasmic membrane-anchored proteins, the glycosyltransferase, Alg8, and the proposed copolymerase, Alg44, are necessary for alginate polymerization (7–9). The MucR sensor protein, a diguanylate cyclase (DGC)/phosphodiesterase (PDE) embedded in the cytoplasmic membrane, was proposed to provide c-di-GMP for binding to the cytoplasmic PilZ domain of Alg44 by which alginate polymerization is activated (10). Translocation of nascent alginate across the periplasm is coupled with modification processes, including O-acetylation and epimerization. O-Acetylation is independently catalyzed by AlgI and AlgX (11), while the acetyl group donor is provided by AlgL and AlgF (12, 13). The AlgG epimerase converts M residues to G residues in the nascent alginate chain. AlgG, AlgX, and AlgK were suggested to form a periplasmic scaffold for guiding alginate through the periplasm for secretion via the outer membrane protein AlgE (14–19). It was also suggested that if alginate is misguided into the periplasm, then degradation would be mediated by the periplasmic AlgL.Iyase (20). Previous studies on protein-protein interactions and mutual stabilities of proposed subunits of the multiprotein biosynthesis machinery provided evidence of binary protein interactions, including AlgE-AlgK, AlgX-AlgK, AlgX-MucD (a serine protease), Alg44-AlgX, and Alg8-AlgG (21, 22). However, more experimental evidence is needed to map all protein-protein interactions within the multiprotein complex, in particular toward unraveling the molecular mechanisms of alginate polymerization, molecular mass control, and the relationship of modification events to polymerization.

In this study, protein-protein interactions within the multiprotein complex were investigated using the bacterial two-hybrid technique and pulldown assays. The proposed interacting protein surface of Alg44 was probed, and the molecular mechanism of c-di-GMP-mediated activation was studied (23, 24). The role of Alg8, Alg44, AlgG, and AlgX with respect to polymerization and modification was studied by analyzing the composition and material properties of alginites produced by various strains. We employed a constitutively alginate-producing strain of \textit{P. aeruginosa} PDD300, to generate isogenic single- and double-gene knockouts of \textit{alg8}, \textit{alg44}, \textit{algG}, and \textit{algX}. This allowed studying the role of the respective proteins in alginate polymerization and/or modifications by introducing additional copy numbers of subunits or their variants in \textit{trans}. The impact of various alginate structures on motility, biofilm formation, and architecture was investigated.

RESULTS

Protein-protein interaction of membrane-anchored Alg8 and Alg44 toward constitution of an active alginate polymerase subunit. The two cytoplasmic membrane-anchored proteins Alg8 and Alg44 were previously shown to be necessary for alginate polymerization. Alg8 is a glycosyltransferase catalyzing alginate polymerization, using the substrate GDP-mannuronic acid, while the c-di-GMP-binding PilZ domain containing Alg44 was proposed as copolymerase (9, 25). However, the functional and structural interactions of Alg8 and Alg44 had not been elucidated. Therefore, the marker-free isogenic double-gene-knockout PDO300\textit{alg8}\textit{alg44} mutant was generated. This mutant lost the mucoid phenotype, while introduction of plasmid pBRR1MCS-5:alg44:alg8 restored alginate production and the mucoid phenotype.

In order to investigate the proposed interaction of Alg8 and Alg44, functional His-tagged variants (Alg44-6His and Alg8-6His) were subjected to pulldown experiments under native conditions and to bacterial two-hybrid system assays. In pulldown experiments, wild-type Alg44 and Alg8 without His tag served as negative controls. To address possible stoichiometric effects, i.e., effects of increased copy numbers of individual subunits on the integrity of the multiprotein complex, single genes encoding Alg8-6His or Alg44-6His under the control of their native promoter were integrated into the genome. In contrast, in \textit{trans} genes were present on plasmids in multiple copies under control of the strong constitutive \textit{lac} promoter. Immunoblots showed that Alg44 with an apparent molecular mass of 41.8 kDa was copurified with Alg8-6His produced either from in \textit{trans} or in \textit{cis} encoding genes, and similarly Alg8 (~53 kDa) was copurified with Alg44-6His, while respective proteins were not detected for complemented mutants with native Alg44 and Alg8 as well as in double-knockout mutants with single Alg8-6His or Alg44-6His (Fig. 1A and B).

In addition, the bacterial two-hybrid system showed that the chimeric enzyme adenylate cyclase was reconstituted when its two complementary fragments (T18/T25) were brought together by Alg8 and Alg44 interaction. \textit{β}-Galactosidase activity in those cells harboring two plasmids producing fusion proteins of Alg8 and Alg44 (pKNT25:alg8-PUT18:alg44) was on average 11-fold (672 U/mg [cellular dry weight]) greater than the negative controls without the fusion protein partner (background control) or compared with single fusion protein Alg8 or Alg44 (58 to 66 U/mg [cellular dry weight]) as well as the vice versa combination (pKNT25:alg44-PUT18:alg8), which showed a \textit{β}-galactosidase activity of 160 U/mg (cellular dry weight) (Fig. 1C). Analysis of cytoplasmic membrane proteins by immunoblotting confirmed that both proteins were localized to the cytoplasmic membrane of \textit{Escherichia coli} (Fig. 1D). These results provided the first experimental evidence for the direct interaction between the membrane-anchored proposed alginate polymerase (glycosyltransferase) Alg8 and the copolymerase Alg44.

Cytoplasmic membrane-anchored Alg44 interacts with outer membrane-anchored AlgK, while Alg44 is critical for structural integrity of the multiprotein alginate biosynthesis machinery. To assess whether Alg8 and Alg44 interact with other proposed subunits of the multiprotein complex, pulldown assays under native conditions were employed using Alg8-6His and Alg44-6His proteins followed by immunoblotting using anti-AlgX, -AlgK, and -AlgE antibodies. Additionally, to rule out indirect interactions, appropriate double-gene-knockout mutants harboring individual genes in \textit{trans} [PDO300\textit{alg8}\textit{alg44} (pBRR1MCS5:alg8-6His), PDO300\textit{alg8}\textit{alg44} (pBRR1MCS5:alg44-6His), and PDO300\textit{alg8}\textit{alg44} (pBRR1MCS5:alg8-6His)] mutants] were included. To address stoichiometric effects, complemented PDO300\textit{alg8} and PDO300\textit{alg44} mutants, respectively, were used to generate single-gene-copy complementation strains by integrating \textit{alg8}-6His and \textit{alg44}-6His into the bacterial genome. The mutants producing native Alg8 and Alg44 proteins were used as negative controls. Resultant immunoblots (Fig. 2A and B) showed AlgK and AlgX but not AlgE were independently
pulled down with Alg44-6His, both when \textit{alg44}-6His was provided in \textit{trans} or in \textit{cis}. Hence, experimental evidence is provided, as previously proposed (21), that a protein-protein interaction network spanning the periplasm and constituted by Alg8-Alg44-AlgK-AlgE interactions exists.

Cross-linking experiments using a DSG cross-linking reagent with a spacer arm length of 7.7 Å followed by Alg44-6His pull-down under denaturing conditions showed a protein with an apparent molecular mass of \textasciitilde 84 kDa, which was detected only by the anti-Alg44 antibody. In addition, the previously shown Alg44-AlgX (21) interaction was confirmed by detecting a cross-linked protein with an apparent molecular mass of \textasciitilde 90 kDa binding both anti-Alg44 and anti-AlgX antibodies. The \textasciitilde 84-kDa protein was detected only in pulldown elution fractions obtained from genomic expression of \textit{alg44}-6His but not from the plasmid-borne gene, while Alg44-AlgX interactions were found to be independent of the stoichiometry of the individual proteins (Fig. 2C and D). These proteins were not detected in elution fractions when the native protein Alg44 was present and in the negative control treated with dimethyl sulfoxide (DMSO).

Alg44 variants with a truncated PilZ domain and C terminus were stable and maintained integrity of protein-protein interactions within the alginate biosynthesis multiprotein complex. Previously, it was demonstrated that site-directed mutagenesis of the putative c-di-GMP-binding motifs (R17XXXR21) of the PilZ domain and a C-terminal truncation of Alg44 completely abolished alginate production (26). In comparison, it was shown that c-di-GMP binds directly to both PgaC and PgaD, the two cytoplasmic membrane of \textit{E. coli} BTH101 (see Materials and Methods). 300, PDO300; 8 and 44, Alg8 and Alg44; MCS5, pBBR1MCS-5; Co+/−, positive/negative control; CDW, cellular dry weight; −18, pUT18; −25, pKNT25. An irrelevant lane was deleted between lanes 2 and 3 in blot A, as indicated by a thin line. Lane 2 in blot B was inserted as a representative control blot lane, as it was obscured by artificial stains in the original blot. Insertion of lane 2 is indicated by thin lines. Between dividing lines in blot B, a representative control blot lane was inserted from a separate blot, because in the original blot, it was obscured by artificial dots/development artifacts.
mucR in the PDO300ΔmucR mutant resulted in greater production of alginate than found in the wild type, while increased copy numbers of rocR encoding a c-di-GMP-degrading phosphodiesterase (PDE) led to strongly reduced alginate production, presumably due to reduction in c-di-GMP levels. Therefore, it was suggested that MucR plays a specific role in the regulation of alginate biosynthesis by colocalizing with Alg44 and providing a localized c-di-GMP pool (10). Here, it was tested if Alg44 copy numbers in the envelope fraction might be affected by the presence or absence of MucR or RocR, respectively, i.e., by different c-di-GMP levels and within different physiological conditions, such as planktonic and biofilm growth modes. Immunoblotting analysis of envelope fractions of the various mutants showed the amount of Alg44 was not significantly affected by the absence of MucR in biofilm mode, while it was reduced in the envelope fraction of biofilm cells with a high copy number of rocR in the absence of MucR (see Fig. S1 in the supplemental material), indicating that the small amount of Alg44 corresponded with low c-di-GMP levels. However, the amount of Alg44 in the same mutants growing in planktonic mode did not significantly differ.

Is alginate polymerization controlled by an autoinhibition mechanism, as shown for the bacterial cellulose synthase Alg8 and BcsA of bacterial cellulose synthase both belong to the glycosyltransferase family 2 (GT-2), and they share the same conserved signature motifs and residues experimentally known as critical for production of alginate and cellulose, respectively (28, 29). Recently, the structure of the bacterial cellulose synthase BcsA-BcsB complex was resolved. It was shown that the PilZ domain in this complex was in proximity to the catalytic site of BcsA (30). The first arginine of the PilZ domain’s R580XXXR584 motif formed a salt bridge with E371 preceding the RW motif (a signature of the glycosyltransferase family 2), consequently tethering the gating loop in the resting status and blocking the catalytic site. This steric hindrance was called the autoinhibiting mechanism, which was proposed to be eliminated upon c-di-GMP binding to R580, opening up the gate for precursors to enter into the catalytic site. Accordingly, informed by the BcsA-BcsB structure and implementing bioinformatics analysis using the Phyre2 Protein Fold Recognition Server, an in silico structural model of Alg8 fused with the C-terminal PilZalg44 domain was developed (31). A structural model homologous to BcsA (confidence, 100%; coverage, 93%) showed the PilZ domain in proximity to the catalytic site of Alg8 and close to the E322, H323, and E326 residues located on the BcsA-homologous loop preceding motif RW (residues 339 and 341).

**FIG 2** Protein-protein interaction analysis indicates interaction of Alg44-AlgK, Alg44-AlgX, and probable Alg44-Alg44 (dimer). (A and B) His tag-based pulldown assays and immunoblotting using anti-AlgK (A) and anti-AlgX (B) antibodies show interactions of Alg44-AlgK and Alg44-AlgX (A and B, lanes 1 to 4). These interactions were detected in both cases of in trans and in cis complementation of mutants with alg44-6His (lanes 2 and 3 of blot A; lanes 1 and 2 of blot B). AlgK was pulled down using His-tagged Alg44 in the absence of AlgX (lane 1, blot A). The elution fraction derived from complemented mutants producing non-His-tagged protein lacked AlgK and AlgX (lane 4 in blots A and B). (C and D) Immunoblots suggesting in vivo Alg44 dimerization and Alg44-AlgX interaction using stabilization of interaction by chemical cross-linking combined with His-tagged Alg44-mediated pulldown assays under denaturing conditions (see Materials and Methods). A presumable Alg44 dimer band (~84 kDa) reacted only with anti-Alg44 antibody (blot C, lane 2) while the alg44-AlgX band (~90 kDa) reacted with Alg44 and AlgX antibodies in both blots (blot C, lanes 2 and 4; blot D, lane 3). These bands were not detected in the elution fraction derived from mutants with native Alg44 with DSG and Alg44-6His treated with DMSO as negative controls (blot C, lanes 1, 3, and 5; blot D, lanes 1 and 4). PDO300; MCS5, BBR1MCS-5; Co+/H1001/H1002, positive/negative control. An irrelevant lane was deleted between lanes 1 and 2 in blot A, as indicated by a thin line.
340), a site potentially involved in salt bridge formation (Fig. 4A to C). The impact of alanine substitutions of these residues, individually and in combination with R17 and/or R21 of Alg44's RXXXR (residues 17 to 21) motif at different c-di-GMP levels (i.e., the presence or absence of overproduced c-di-GMP degrading RocR), on in vivo activity of respective Alg8 and Alg44 variants was assessed. The overproduction of RocR was confirmed to significantly reduce alginate production in the wild-type strain and complemented mutants. Substitution of R residues in the PilZAlg44 domain RXXXR motif (amino acids 17 to 21) and the E322 residue...
due of Alg8 with alanine completely abolished alginate production. The mutagenesis of H323 [i.e., PDO300\textsuperscript{alg8} (pBBR1MCS-5::alg8 (H323A) mutant)] lowered alginate production by 6.9-fold compared to that of the PDO300\textsuperscript{alg8} (pBBR1MCS-5::alg8) mutant. Interestingly, RocR-mediated reduced intracellular c-di-GMP levels restored alginate production to PDO300\textsuperscript{alg8} (pBBR1MCS-5::alg8rocR) mutant levels (Fig. 4D, labeled with asterisk). Replacement of E326 by alanine in Alg8 increased alginate production by 1.3-fold compared with that of the PDO300\textsuperscript{alg8} (pBBR1MCS-5::alg8) mutant. RocR production in this mutant background mediated decreased alginate production by about 2-fold compared to that of wild-type Alg8 (Fig. 4D). In summary, conserved R residues of Alg44 proposed to be involved in autoinhibition via salt bridge formation inactivated alginate polymerization. However, the replacement of H323 or E326 of Alg8 still mediated alginate production, while reduced levels of c-di-GMP did cause less or no reduction of alginate production compared to that of the reference strain PDO300\textsuperscript{alg8} (pBBR1MCS-5::alg8) mutant.

\textsuperscript{a} PDO300; MCS5, pBBR1MCS-5; \(F_G\), molar fraction of guluronate (G) residue; \(F_M\), molar fraction of mannuronate (M) residue; \(F_{GAMAG}\), molar fraction of two consecutive G and M residues; \(F_{SM}\), molar fraction of two consecutive M residues; Ac, acetylation; PI, polydispersity index; CDM, cell dry mass.

\(\text{Alg8}\) and \(\text{Alg44}\) were introduced into respective mutant backgrounds. Additional copies of \(\text{Alg8}\) and/or \(\text{Alg44}\) had a similar effect on alginate production, such as resulting in high molecular masses with reduced epimerization and acetylation compared to those of the wild-type control (Fig. 5A; Table 1). The same effect of \(\text{Alg8}\) and \(\text{Alg44}\) on alginate polymerization supported the hypothesis that both subunits constitute the alginate polymerase.

\(\text{AlgF}\), \(\text{AlgG}\), and \(\text{AlgI}\) were proposed to form a protein complex constituting the alginate acetyltransferase/acetyltransferase (12, 32, 33). Recently, \(\text{AlgX}\) was demonstrated to play an independent role in alginate acetylation. \(\text{AlgX}\) is a two-domain protein, including a catalytic and a carbohydrate-binding domain. Replacement of amino acid residues S269, H176, and D174, which were proposed to constitute the catalytic site, resulted in nonacetylated alginate (13). \(\text{AlgG}\), the epimerase, contains a conserved DPHD motif (residues 324 to 327) (14, 19, 34, 35), the proposed active site involved in epimerization. Replacement of amino acid residues in this motif was shown to result in nonepimerized alginate, while modified \(\text{AlgG}\) retained its protective role on nascent alginate against degradation in the periplasm. Here, we used catalytically inactive variants of \(\text{AlgX}(\text{S269A})\) and \(\text{AlgG}(\text{D324A})\). When only the inactive \(\text{AlgX}\) variant was present, the resulting alginate was nonacetylated. Interestingly, additional copies of active \(\text{AlgX}\) or inactive \(\text{AlgX}\) resulted in the highest epimerization values of molar fraction of G residue (\(F_G\)) = 0.36. Additional copies of both \(\text{AlgG}\) and \(\text{AlgX}\) or inactive variants increased the degree of epimerization of the resulting alginate (Fig. 5A). Additional copies of both \(\text{AlgG}\) and \(\text{AlgX}\) increased the degree of acetylation compared to additional copies of only \(\text{AlgX}\) (Fig. 5A). Interestingly, additional copies of \(\text{Alg44}\) enhanced acetylation 2.7-fold compared to \(\text{AlgX}\).

The correlation between the molecular mass of alginate and alginate modification, such as acetylation and epimerization, was assessed (Fig. 5B). The molecular mass of the various alginates was determined by size exclusion chromatography-multianalyte light scattering (SEC-MALLS) (Table 1; see also Fig. S3 in the supplemental material). The highest molecular mass (4,653 ± 1.1% kDa, corresponding to about 22,876 uronic acid residues) was detected in alginates from strains with additional copies of the catalytically inactive epimerase variant \(\text{AlgG}(\text{D324A})\). This was about a 70% increase in molecular mass compared to alginate produced from strains with additional copies of epimerizing...
AlgG. The lowest-molecular-weight alginates were produced by strains harboring additional copies of those subunits contributing the highest levels of epimerization, i.e., AlgX (F\(_{G}\) = 0.36) and AlgX(S269A) (F\(_{G}\) = 0.36), along with the lowest levels of acetylation (9.8% and 0). Nonacetylated and nonepimerized alginates (F\(_{G}\) = 0, acetylation = 0%) showed the lowest molecular mass (1,811 ± 0.9% kDa). Since \(^1\)H-NMR spectra of the various alginates did not provide evidence for double bonds (between the C-4 and C-5 carbons, leading to 4-deoxy-L-erythro-hex-4-enopyranosyluronic acid), which are introduced by alginate lyase-mediated degradation, the alginate lyase presumably did not influence the polymerization degree. Additional copies of Alg8 and Alg44 gave rise to increased molecular masses ranging from 3,000 to 3,800 kDa, supporting their direct involvement in alginate chain synthesis. These data suggested that the alginate molecular mass is inversely correlated with alginate epimerization but positively correlated with acetylation (Fig. 5B). Alginates produced by the various strains showed a narrow mo-

**FIG 5** Impact of putative alginate polymerase subunits on alginate polymerase activity, alginate polymerization, and composition and correlation between polymerization and modification. (A) The values of molar fraction of G residue (F\(_{G}\)), acetylation degrees (Ac. %), mean molecular masses, and alginate yield are aligned with the strains producing the respective alginates. (B) Correlation between degree of acetylation, epimerization, and molecular mass of alginate. Presumable features (no. 1 to 11) show protein complexes constituted by Alg8, Alg44, AlgG, and AlgX (see the legend at the top left corner of the plot). The subunit produced upon in trans complementation is shown as darker shape(s). Inactive AlgX(S269A) and AlgG(D324A) proteins are labeled as (Ac\(^-\)) and (Ep\(^-\)), respectively. The length of various alginates (PD) with respect to acetylation (Ac. %) and epimerization (F\(_{G}\)) degrees are presented and proportionally illustrated for each feature. 300, PDO300; MCS5, pBBR1MCS-5; PD, polymerization degree; OM, outer membrane; CM, cytoplasmic membrane.
molecular mass distribution with a polydispersity index close to 1 (Table 1).

**In vivo alginate polymerase activity.** Alginate produced by the various strains was isolated and quantified (Fig. 5A; Table 1). Although additional copies of the various proteins increased the amount of alginate produced compared to the PDO300 (pBBR1MCS-5) reference strain, a significant variation of alginate productivity, i.e., alginate polymerase activity, was detected. Interestingly, additional copies of nonacetylating AlgX(S269A) and native AlgX mediated production of the largest amounts of alginate, while epimerizing and nonpimerizing AlgG mediated the lowest level of production (Fig. 5A). Pairwise comparison of these four strains showed that more alginate is produced in the absence of modification events. The enhancing role of AlgX in alginate production was further supported when additional copies of AlgX together with AlgG led to a strong production of alginate. However, the nonacetylating and nonpimerizing pair of them resulted in a much lower quantity (Fig. 5A). Furthermore, all attempts to restore alginate production in the PDO300Δalg44ΔalgX mutant with pBBR1MCS-5:alg44algX failed. The mucoid phenotype of this double-gene-knockout mutant was restored only when one of the introduced complementing genes, either alg44 or algX, was integrated into the genome (in cis complementation using mini-CTX) and the other one presented in trans, resulting in alginate production of 1.9 g/cell dry mass (CDM) (g).

**Microrheological analysis of various alginates.** Particle-tracking microrheology was applied to assess the viscoelastic properties of the various resulting alginates. All alginates showed viscoelastic properties in which the solid-like elastic modulus G' was greater than the liquid-like viscous modulus G" (G' > G''). The plot of particle mean square displacement (MSD) versus correlation time showed MSD curves of the alginates are distributed in four distinct categories (see Fig. S4 in the supplemental material). In the first category, the alginates produced from the PDO300ΔalgG(pBBR1MCS-5:algG(D324A)) and PDO300Δalg8 (pBBR1MCS-5:alg8) mutants, without G residues and with the highest molar fraction of MM-blocks, respectively, and both with very high molecular mass, showed the highest and quite similar viscoelastic properties (G' = 0.41, G'' = 0.3; G' = 0.40, G'' = 0.28, respectively). Interestingly, the alginates from the PDO300Δalg44 (pBBR1MCS-5:alg44), PDO300ΔalgG(pBBR1MCS-5:algG), and PDO300(pBBR1MCS-5) strains dropped into the second category with lower viscoelastic properties. In the third category, showing lower viscoelastic properties, those alginates with a molecular mass of ≈2,000 kDa produced by PDO300ΔalgX(pBBR1MCS-5:algX(S269A)) and PDO300ΔalgXΔalgG(pBBR1MCS-5:algX(S269A):algG(D324A)) mutants were found. Surprisingly, acetylated alginate from the PDO300ΔalgX(pBBR1MCS-5:algX) mutant was the only member of the fourth category, with the lowest viscoelastic property among all analyzed samples. These results suggested that viscoelasticity was positively impacted by the molecular mass combined with high M content, while the presence of G residues and acetyl groups in the alginate chain lowered viscoelasticity. All these polymers showed greater elasticity than viscosity (G' > G'').

**The impact of various alginates on biofilm formation.** *P. aeruginosa* is capable of different modes of motility, such as twitching, swarming, and swimming, which are controlled by various regulatory pathways and environmental factors. These play an important role in biofilm formation and dispersal. Here, motility assays were conducted with strains capable of producing different alginates in order to assess the relationship between alginate composition/molecular mass, i.e., material properties, and motility, ultimately impacting on biofilm formation (see Fig. S5 in the supplemental material). All strains with alginate production greater than that of PDO300 (pBBR1MCS-5) showed lower twitching motility, while non-alginate-producing knockout mutants showed greater twitching values. The lowest twitching motility among all strains was found for the PDO300Δalg44(pBBR1MCS-5:alg44) mutant. Twitching motility differences between the PDO300ΔalgX (pBBR1MCS-5:algX) and PDO300ΔalgX(pBBR1MCS-5:algX(S269A)) mutants or between the PDO300ΔalgG(pBBR1MCS-5:algG) and PDO300ΔalgG(pBBR1MCS-5:algG(D324A)) mutants were insignificant (see Fig. S5 in the supplemental material).

Swarming motility, which occurs on semisolid surfaces and is regulated by quorum sensing, was assessed as being lower in alginate-producing strains than in their respective knockout mutants, except for the PDO300Δalg8(pBBR1MCS-5:alg8) mutant, which showed slightly greater swarming motility than the PDO300ΔalgG(pBBR1MCS-5) mutant. Among the alginate-producing strains, the greatest value of swarming motility was found for the PDO300Δalg44(pBBR1MCS-5:alg44) mutant (11.33 mm) and the PDO300ΔalgX(pBBR1MCS-5:algX) mutant (11.0 mm). The PDO300ΔalgG(pBBR1MCS-5:algG(D324A)) mutant (6.83 mm) showed slightly greater swarming motility than the PDO300ΔalgG(pBBR1MCS-5:algG) mutant (6.0 mm).

Swimming, which occurs in aqueous environments, was tested, and the values obtained varied significantly among the strains. Generally, alginate-producing strains showed lower swimming capability than knockout mutants, except for the PDO300Δalg8(pBBR1MCS-5:alg8) and PDO300ΔalgG(pBBR1MCS-5) mutants (see Fig. S5 in the supplemental material).

Confocal laser-scanning microscopy images of biofilms formed by the PDO300ΔalgX(pBBR1MCS-5:algX) mutant and its nonacetylating counterpart, the PDO300ΔalgX(pBBR1MCS-5:algX(S269A)) mutant, highlighted the crucial role of acetylation of alginate for developing biofilms and cellular arrangements (Fig. 6). For example, the structures formed by strains producing acetylated alginates were perfectly shaped and developed with a biovolume of 5.5 ± 1.26 μm³ · μm⁻² and a maximum height of 83 μm, while those formed with nonacetylated alginate showed a smaller biovolume of 3.9 ± 0.2 μm³ · μm⁻² and a reduced height of 26 μm, with irregular architecture. Interestingly, the strain producing acetylated alginate did not produce a multicellular base layer, and cells were organized in pillar-shaped architectures, similar to structures described for the architectures of the PsI-overproducing strain (i.e., *P. aeruginosa* WFP801) (36, 37). In contrast, the strain producing nonacetylated alginate formed a biofilm with disordered and scattered microcolonies (Fig. 6, frame 3). Furthermore, the PDO300ΔalgX(pBBR1MCS-5:algX) mutant formed a biofilm with 1.5-fold more compactness and 31% more live cells than the biofilm formed by the PDO300ΔalgX (pBBR1MCS-5:algX(S269A)) mutant (Table 2). The PDO300ΔalgX (pBBR1MCS-5) mutant did not form a structured biofilm (Fig. 6, frame 4) but did form a multicellular layer with a thickness of 6 μm.
which produced a high-molecular-mass, acetylated polymannuronate with strong viscoelasticity, acquired the largest biovolume of $6.0 \pm 0.22 \ \mu m^3/\mu m^2$ (Fig. 7, frame 3). Interestingly, adjacent structures were networked with horizontal appendages, with void spaces and channels formed underneath whole structures, likely to constitute water channels (Fig. 7, frame 4). On the other hand, the PDO300$\Delta algG$(pBBR1MCS-5:algG) mutant, which produced lower-molecular-mass, acetylated, and G residue-containing alginate, formed elevated but less developed structures with less biovolume, $4.8 \pm 0.22 \ \mu m^3/\mu m^2$ (Fig. 7, frame 1). The base layers formed by both strains were dense and covered the whole area of the surface. The biofilm of the PDO300$\Delta algG$(pBBR1MCS-5) mutant was a homogenous layer of cells (7-$\mu m$ thickness) without elevated structures (Fig. 7, frame 2).

The PDO300$\Delta algG\Delta algX$(pBBR1MCS-5:algX(S269A):algG (D324A)) mutant produced a nonacylated polymannuronate with a low molecular mass, and the respective biofilm was composed of very long and narrowly elevated structures (Fig. 8, frames...
TABLE 2  Compactness and dead/live ratio calculated for analyzed biofilms

| Mutant description | Compactness | Dead/live ratio |

1 and 2). The biovolume was 1.5 ± 0.2 μm³ · μm⁻², which was less than for all the other investigated strains (Table 2).

The PDO300Δalg8(pBBR1MCS-5:alg8) and PDO300Δalg44 (pBBR1MCS-5:alg44) strains established heterogeneous highly structured biofilms (Fig. 9). The former formed a biovolume of 3.95 ± 0.43 μm³ · μm⁻² and compactness of 6.09E+02, while the latter generated very dense and large structures with a biovolume of 5.8 ± 0.43 μm³ · μm⁻² but less compactness (4.43E+02). Both mutants showed higher numbers of dead cells than all applied mutants but fewer dead cells than the wild type (Table 2). Conversely, the PDO300Δalg8(pBBR1MCS-5) and PDO300Δalg44 (pBBR1MCS-5) strains generated homogenous biofilm without elevated or highly structured architectures. Compactness values and dead/live ratios are summarized in Table 2.

DISCUSSION

In this study, we investigated the relationship between alginate polymerization and modification, the functional role of the subunits Alg8, Alg44, AlgG, and AlgX, and their physical and functional interaction. A range of alginate compositions and molecular masses exhibiting various material properties were produced by engineered P. aeruginosa strains, and their impact on motility and biofilm formation was assessed. This study revealed protein-protein interaction between Alg8 and Alg44, proposed as alginate polymerase and copolymerize (Fig. 1). Alg44 was found to interact with AlgK (Fig. 2A), which is an outer membrane lipoprotein that aids the correct localization of the AlgE porin to the outer membrane. This study provides experimental evidence for the previously suggested presence of an Alg8-Alg44-AlgX-AlgK-AlgE multiprotein complex bridging the cell envelope forming the alginate polymerization/modification/secretion machinery (21). The absence of the previously observed AlgK-X interaction after DSG cross-linking and anti-AlgX immunoblotting (Fig. 2D) was presumably due to a lack of suitable cross-linking sites (K residues 7 Å apart from each other) (22). In addition, immunoblotting/cross-linking data suggested that Alg44 forms a dimer. However, this dimer was not observed when Alg44 was overproduced from a plasmid, indicating that Alg44 dimerization might be susceptible to changes in stoichiometry (Fig. 2C and D). Bioinformatics analysis of the periplasmic part of Alg44 suggests the presence of coiled structures (Coil/Pcoils-based score of 0.4), which have been described for membrane fusion proteins (MFPs) such as MexA and polysaccharide copolymerases (PCPs) to contribute to oligomerization (38). Here, it was demonstrated that Alg44 localization, stability, and protein-protein interaction were not impacted by altering the c-di-GMP level or by non-c-di-GMP binding variants (Fig. 3; see also Fig. S1 in the supplemental material). Our results indicated that the c-di-GMP-mediated activation mechanism of alginate polymerization differs from the activation mechanism of cellulose synthase in which c-di-GMP releases an autoinhibited state by breaking a salt bridge (30). However, residue H323 of Alg8 might be involved in c-di-GMP-dependent activation of alginate polymerase, as reduced c-di-GMP levels did not impair in vivo Alg8 activity (Fig. 4).

The first experimental evidence was obtained that AlgX and AlgG exhibit a mutually auxiliary behavior, suggesting that the two modification events (acetylation and epimerization) are not competitive but linked (35). In addition, we propose a new auxiliary role for Alg44 in acetylation besides being necessary for c-di-GMP-dependent activation of alginate polymerization (Table 1; Fig. 5A). Failed attempts in complementing the PDO300Δalg44 ΔalgX mutant with pBBR1MCS-5:alg44algX, but successful complementation if one gene was present in cis and the other in trans, suggested that the stoichiometry of these two proteins is critical for proper performance of the multiprotein complex.

This study revealed how alginate polymerization (Alg8, Alg44) is aligned with alginate modification (AlgG, AlgX). As shown in Fig. 5A, additional copies of active or inactive AlgX acetyltansferase significantly increased the molar fraction of G residues as well as productivity, which appeared inversely correlated with the alginate molecular mass (Fig. 5A; Table 1). This suggests a new role of AlgX in epimerization and a periplasmic scaffold protein playing a key role in efficient translocation of the alginate chain across the periplasm. Recently, it was reported that AlgX binds to polymannuronic acid in a length-dependent manner and acts as a terminal acetyltansferase (11).

Interestingly, restoration of alginate production of the AlgG-negative mutant by an inactive variant of AlgG led to a significantly increased alginate molecular mass compared to that of active AlgG, suggesting that AlgG as a scaffold subunit is critical for processivity of alginate polymerization, while the actual epimerization event interferes with processivity (Fig. 5A and B). Furthermore, the role of AlgG-mediated epimerization on alginate length might be due to AlgG-mediated alginate degradation, as polysaccharide epimerases show a reaction mechanism similar to that of polysaccharide lyases (35). This finding might also explain why algal alginates with a high molar fraction of G residues introduced by epimerases have very low molecular masses (39). Acetylation was correlated with the molecular mass, suggesting that there was no impact on processivity of alginate polymerization (Fig. 5B).

In general, additional copies of any subunit increased alginate production compared to that of the reference strain, indicating that the stoichiometry of the various subunits is less critical for the activity of the multiprotein complex (Table 1). Based on these results with regard to the roles of the investigated subunits in alginate synthesis and modification, a revised model of the alginate biosynthesis multiprotein complex was proposed (Fig. 10).

To shed light on the structure-function relationship of the various alginites, their viscoelasticity was assessed. The presence of...
Acetyl groups lowered viscoelasticity by possibly interfering with intermolecular alginate chain interactions (see Fig. S4 in the supplemental material). In contrast, increasing molar fractions of MM-blocks and higher molecular masses increased viscoelasticity (see Fig. S4 in the supplemental material). Acetylated alginates gave rise to well-developed and highly organized heterogeneous architectures and promoted cell aggregations (Fig. 6), which was consistent with previous studies (40), but these findings suggested viscoelasticity is not critical for biofilm architecture formation. Figure 7 shows that nonepimerized alginate (polymannuronate)
FIG 8 Biofilm architecture of mutant-producing nonpimerized and nonacetylated alginates and the wild type. This figure shows biofilm formation and architecture of the PDO300ΔalgXΔalgG(pBBR1MCS-5:algX(S269A):algG(D324A)) (frames 1 and 2) and PDO300(pBBR1MCS-5) (frame 3) mutants. In all frames, A, B, and C show, respectively, top views, side views, and a representative of typical highly structured cell communities for that mutant with biovolume-per-area (µm³/µm²) ratio. The biofilm architecture visualized for the mutant producing nonacetylated poly(M) alginate (frames 1 and 2) was remarkably different from that of other applied mutants. Affected by alginate properties, emerging biofilm consists of very narrow but long elevated microcolonies representing longitudinal cell trails or strips indicating stigmergic self-organization and adaptation of cells in weak matrices. Frames 2D to F represent close side and top views of one of the microcolonies and cell trails, and cell-cell interactions in each cell trail are depicted in sketches. Frames 2G to J show micrographs (×40 magnification) of the edge (H and I) and surface (G and J) of mucoid colonies of the PDO300ΔalgXΔalgG(pBBR1MCS-5:algX(S269A):algG(D324A)) (G and H) and PDO300(pBBR1MCS-5) (I and J) mutants forming a thin layer on PIA medium after incubation at 37°C for 18 h. Organization of cells of the PDO300ΔalgXΔalgG(pBBR1MCS-5:algX(S269A):algG(D324A)) mutant showed a linear filamentous aggregation pattern. Wild-type biofilm architecture is presented in frame 3.
with high molecular mass and the strong viscoelasticity supported the establishment of these biofilm features and that by controlling the molar fraction of G residue biofilm architecture, characteristics could be adapted to various environments. We showed that the lack of G residues and acetyl groups caused the formation of undeveloped and narrow microcolonies, which were supported by specific long trails or strips of cells emerging from stigmergic self-organization of cells affected by this particular alginate.
This was further evidence for the role of alginate material properties on the formation of particular biofilm architectures and cellular aggregation patterns.

Motility mediated by twitching, swarming, and swimming was assessed using strains producing various alginites. These motilities are critical for biofilm development and dispersal (42). Here, we showed that overproduction of alginate interferes with motility. Previously, it was shown that high levels of c-di-GMP reduced motility while increasing production of various exopolysaccharides and biofilm formation (43). Moreover, our results showed these motilities are independent of the acetyl group and G residue content of the respective alginate (see Fig. S5 in the supplemental material). Overall, this study led to updating the protein-protein interaction network constituting the proposed alginate polymerization/modification/secrection multiprotein complex in *P. aeruginosa* and the development of strains producing a range of alginites, enabling the analysis of structure-function relationships from a material property and biological function perspective, such as demonstrating that viscoelasticity of alginate contributed to enhanced cell aggregation during biofilm formation.

**MATERIALS AND METHODS**

**Bacterial strains, plasmids, and growth conditions.** Strains and plasmids used in this study are summarized in Table S1 in the supplemental material. *P. aeruginosa* and *Escherichia coli* strains were grown at 37°C. For those assays designed for studying alginate production, bacterial phenotype, and protein-protein interaction and stability, Difco *Pseudomonas* isolation agar (PIA) medium was used. To rule out the effect of growth condition and media on alginate composition and quantity, all experiments were conducted under the same conditions and using the same batch culture at the same time (see the supplemental material).

**Construction of isogenic mutants with single- and double-gene knockouts of alg8, alg44, algG, and algX genes.** The *P. aeruginosa* PDO300 strain was used to generate isogenic mutants with single- and double-gene knockouts of alg8, alg44, algG, and algX genes through two events of homologous recombination using suicide plasmid pEX100T containing knockout genes which were disrupted by the *aacC1* gene (en-
coding gentamicin acetyltransferase) flanked by two FRT sites (see the supplemental material).

In trans complementation of single- and double-gene-knockout mutants and chromosomal integrations. Relevant genes encoding Alg8, Alg44, AlgG, and AlgX (with and without the 6His tag) were individually or in combination transferred into generated mutants using the pBBR1MCS-5 plasmid and also incorporated into the genome using mini-CTX-lacZ plasmid (see the supplemental material). The pBBR1MCS-5 plasmid containing various alginates was considered to study the impact on production of alginate and their characteristics in order to more sensitively detect changes in the alginate due to additional copy numbers of the respective alginate protein under investigation.

Site-specific mutations and deletions of alg44 and alg8. Site-specific mutations and deletions of alg44 and alg8 genes were performed using the QuikChange II site-directed mutagenesis kit (Stratagene) or by DNA synthesis (GenScript), resulting in genes encoding the Alg8(E322A/H323/E326A) protein, Alg44(R17A/R21A/R21D) protein, and Alg44’s N- and C-terminal truncation (see the supplemental material).

In vivo detection of the protein-protein interaction network. In vivo detection of protein-protein interaction was performed by employing pulling down 6His-tagged proteins under native conditions, in vivo chemical cross-linking, and bacterial two-hybrid assay (see the supplemental material).

Assessment of the stability of Alg44 variants in the presence and absence of MucR (DGC/PDE)/RocR (PDE). Previously generated mutants, including the PDO300 ΔmucR, PDO300ΔmucR(pBBR1MCS-5: mucR), PDO300pBBR1MCS-5:ΔmucR and PDO300ΔmucR(pBBR1MCS-5:rocR) mutants, were shown to positively or negatively regulate alginate production through c-di-GMP synthesis (by MucR) or degradation (by RocR) (24). Also to use presumably nonfunctional Alg44 in binding to c-di-GMP and/or in alginate polymerization (8, 26), the PDO300 Δalg44(pBBR1MCS-5:alg44[R21D]-6His), PDO300Δalg44(pBBR1MCS-5:alg44-6His[Δ46-74aaPilZ]), PDO300Δalg44(pBBR1MCS-5:alg44-6His[Δ364-389aa]) mutants were generated. Using these mutants, we examined the direct effect of c-di-GMP and defective variants of Alg44 on its localization and stability in planktonic and biofilm cells. Cells grown on solid media or in liquid cultures as described above were washed twice with saline. Enzymatic cell lysis was performed using the abovementioned lysis buffer prepared in buffer A followed by sonication and isolation of lysis buffer prepared in buffer A followed by sonication and isolation of extracellular alginate. Enzymatic cell lysis was performed using the abovementioned lysis buffer prepared in buffer A followed by sonication and isolation of extracellular alginate.

Alginate Purification and Quantification. Alginate solutions were dialyzed (12- to 14-kDa molecular mass cutoff; ZelluTrans/Roth mini dialyzer; Carl Roth GmbH & Co.) against 5 liters of ultrapure H₂O for 48 h. Finally, algamines were precipitated with an equal volume of ice-cold isopropanol and freeze-dried for uronic acid assay and biochemical analysis (see the supplemental material).

The analysis of molecular mass, composition, and viscoelastic properties of the alginites. Various alginites produced by different complemented mutants were subjected to molecular mass analysis using size exclusion chromatography-multicycle laser light scattering (SEC-MALS) and compositional analysis utilizing 1H-nuclear magnetic resonance (NMR) spectroscopy and Fourier transform infrared (FTIR) spectrometry (see Text S1 in the supplemental material). Microrheological analysis was used to measure the viscoelastic property of the alginites in which the mean square displacement (MSD) of probe particles embedded in the samples and in turn the viscoelastic moduli (G’ [elastic] and G’’ [viscous]) were measured (see the supplemental material).

Continuous-culture flow cell biofilms, quantitative analysis, and motility assays. Biofilm architecture analysis was performed for those mutants producing alginites with very distinct composition and properties from each other, including the PDO300(pBBR1MCS-5), PDO300 Δalg8/pBBR1MCS-5:alg8, PDO300Δalg44(pBBR1MCS-5:alg44), PDO300 ΔalgG(pBBR1MCS-5:algG), PDO300ΔalgG(pBBR1MCS-5:algG[D324A]), PDO300ΔalgX(pBBR1MCS-5:algX), PDO300ΔalgX[pBBR1MCS-5:algX(S269A)], and PDO300ΔalgXalgG(pBBR1MCS-5:algX(S269A):algG(D324A)) mutants. Each mutant was grown in continuous-culture flow cells (channel dimensions of 4 mm by 40 mm by 1.5 mm) at 37°C (45). The flow cells were then incubated at 37°C for 24 h. Biofilms were stained utilizing the LIVE/DEAD BacLight bacterial vitality kit (Molecular Probes) and visualized using confocal laser scanning microscopy (Leica SP5 DM6000B). For quantitative analysis of biofilms, IMARIS image analysis software (Bitplane) was employed. Biofilm architecture and appearance, biovolume (µm³), the ratio of biovolume per unit area (µm² × µm⁻²), dead-to-live ratio, compactness, and thickness of base layers were analyzed (46–48). Motilities, including twitching, swarming, and swimming, were assessed by the method explained by Pang et al. (42) with modification. Full experimental details are provided in the supplemental materials.
