We report the observation of a frequency shift and splitting of the electron spin resonance (ESR) mode of the low-dimensional $S=1/2$ frustrated antiferromagnet Cs$_2$CuCl$_4$ in the spin-correlated state above the ordering temperature 0.62 K. The shift and splitting exhibit strong anisotropy with respect to the direction of the applied magnetic field and do not vanish in zero field. The low-temperature evolution of the ESR is a result of modification of the one-dimensional spinon continuum by the uniform Dzyaloshinskii-Moriya interaction (DM) within the spin chains.

Relentless search$^1$ for fractionalized spin-1/2 magnetic excitations - spinons - has yielded several clear-cut ‘sightings’ of them in magnetic insulators. The experimental probes include inelastic neutron scattering (INS)$^2$, thermal conductivity $^2$ and $^3$ and photoemission$^4$. Most of the investigated materials possess a very high degree of one-dimensionality (1D) making them a natural ‘habitat’ for spinons, which are extended spin-1/2 domain-wall excitations. More recently it has been realized that 1D spinons can be present in a higher-dimensional setting as well$^5$. INS studies of which uncovered an extensive two-spinon continuum$^6$. Most of the INS spectral intensity is found to be carried by spinons with large momenta. Our work describes an entirely novel, ESR-based way to probe the width and shape of the spinon continuum at small momenta. In doing so we establish a rather unexpected connection of the problem of spinon excitations in the Heisenberg spin chains subject to the uniform Dzyaloshinskii-Moriya (DM) interaction with that of electrons in semiconductor heterostructures subject to the spin-orbital interaction of Rashba-type$^7$, $^8$, $^9$.

Cs$_2$CuCl$_4$ realizes distorted triangular lattice with strong exchange $J$ along the base of the triangular unit and weaker exchange integral $J'=0.34J$ along lateral sides of the triangle. The material orders below $T_N = 0.62$ K into a long-range 3D spiral state$^{11}$. The $T_N$ is far below the Curie-Weiss temperature $T_{CW}=4$ K. In the intermediate temperature range $T_N < T < T_{CW}$ a spin-liquid phase with strong in-chain spin correlations takes place. Both the dynamic spin structure factor$^8$ and the low-temperature phases$^7$ of Cs$_2$CuCl$_4$ are well described by a quasi-1D model of weakly coupled spin $S=1/2$ chains, extended in$^9$ to include crucial symmetry-allowed DM interactions between the spins.

ESR is well known as a method providing fine details of spin excitation spectra at small momenta in both ordered and paramagnetic$^{18,19}$ phases. Here we uncover dramatic sensitivity of the ESR and spinon spectra to the uniform DM interaction in the spin-liquid phase of Cs$_2$CuCl$_4$. We observe and explain splitting of the ESR mode into two modes with lowering the temperature, as well as its remarkable polarization anisotropy.

The crystal samples were grown by two methods. First set of samples was prepared by the crystallization from the melt of a stoichiometric mixture of CsCuCl$_3$ and CsCl in an ampule, which was slowly pulled from the hot ($T=520^\circ$ C) area of the oven. The second method was crystallization from solution$^2$. The room temperature crystal lattice parameters for both sets of crystals are $a=9.756$ Å, $b=7.607$ Å, $c=12.394$ Å. The samples obtained by last method have natural faces and are lengthened along b-axes. Both sets of crystals demonstrated identical ESR signals. The study in the frequency range 9-90 GHz was performed with a set of homemade spectrometers equipped with cryomagnets. The resonance lines were taken at the fixed frequency, as dependences of $H$ and orientation of the external magnetic field $|g_i|=20,02$ were obtained by pumping vapor of $^4$He ($^3$He), correspondingly. Cooling down to 0.1 K was achieved with the help of a dilution cryostat Kelvinox-400.

At temperatures above $T = 10$ K we observe conventional paramagnetic resonance with a single narrow line corresponding to $g$-factor values $g_a = 2.20 \pm 0.02$, $g_b = 2.08 \pm 0.02$, $g_c = 2.30 \pm 0.02$. These $g$-factor values agree well with those reported earlier at $T = 300$ K and $77$ K$^{21}$, and, for $g_c$, at $T = 4.2$ K$^{22}$.

Significant evolution of the ESR spectrum was found on cooling below 6 K. This evolution depends strongly on the microwave frequency $\nu$ and orientation of the external magnetic field $H$. For $H \parallel b$, we observe a single Lorentzian line shifting with cooling to lower fields
fitted by the frequency-field relation of an ordered antiferromagnet with “gap” $\Delta/(2\hbar) = 14$ GHz at $T=1.3$ K, 

$$2\pi\hbar\nu = \sqrt{(g\mu_B H)^2 + \Delta^2}.$$  \hspace{1cm} (1)

(ii) For $H \parallel a, c$, the ESR line strongly broadens on cooling, and its shape distorts, as shown in the inserts of Fig. 2. The absorption at $T=1.3$ K may be fitted by a sum of two Lorentzians, indicating the splitting of the resonance mode. The $\nu(H)$ dependence at $H \parallel a$ is presented in Fig. 2. Two modes at $T = 1.3$ K were resolved for measurements in the frequency range 14-50 GHz. Similar splitting was reported previously in \[2\]. At higher frequencies the splitting is masked by natural linewidth, which prevents the resolution of the doublet, while at lower frequencies the signal becomes too broad. The angular dependence of the resonance field $H_r$ in the $ab$ plane for $\nu = 27$ GHz at $T = 1.3$ K. Thick line is the theoretical prediction with $D_{ab}/(4\hbar) = 8$ and $D_{ab}/(4\hbar) = 11$ GHz. The measured values of the resonance field deep in the paramagnetic phase (at $T = 10$ K) are presented by crosses, the dashed line is a theoretical fit of a paramagnetic resonance with $g_{a,b,c}$. At lower frequencies, we observe a strong decrease of the intensity with cooling, and no visible shift from the paramagnetic resonance field, in contrast to ESR lines taken at $\nu > 17$ GHz, which exhibit a shift and do not lose intensity on cooling. At $\nu = 9$ GHz the integral intensity at $T=1.3$ K is a half of that at $T=4$ K. The resonant frequencies above 14 GHz may be well fitted by the frequency-field relation of an ordered antiferromagnet with “gap” $\Delta/(2\hbar) = 14$ GHz at $T=1.3$ K, 

$$2\pi\hbar\nu = \sqrt{(g\mu_B H)^2 + \Delta^2}.$$  \hspace{1cm} (1)

(iii) We have also studied polarization dependence of the ESR absorption at $H \rightarrow 0$. Fig. 3 shows ESR records at $T = 1.3$ K and $T = 6$ K for different orientations of the microwave and static fields with respect to the crystal axes, but with $h \parallel H$, at the frequency $\nu = 14$ GHz. At $T \geq 6$ K both the position and the lineshape of the paramagnetic resonance line are the same for all three principal polarizations of the microwave field. However, at $T = 1.3$ K, the absorption in zero field for $h \parallel b$ is at least three times more intensive than for $h \parallel a, c$.

The above observations strongly distinguish Cs$_2$CuCl$_4$ from other known $S = 1/2$ antiferromagnets such as a conventional 3D magnet and a critical quantum spin
chain. The former exhibits an energy gap which van-ishes at the ordering temperature, while the latter shows an ESR shift due to an anisotropic exchange and/or a staggered DM interaction, but only in a presence of the external magnetic field. Unlike Cs$_2$CuCl$_4$, these systems do not exhibit a finite frequency gap for $H=0$ and a direction-dependent splitting of the ESR line, all in the paramagnetic phase.

We now show that all these unusual features follow from a quasi-1D nature of Cs$_2$CuCl$_4$ and the uniform structure of the DM interaction. Our Hamiltonian

$$\mathcal{H} = \sum_{x,y,z} \left( JS_{x,y,z} \cdot S_{x+1,y,z} - D_{y,z} \cdot S_{x,y,z} \times S_{x+1,y,z} + g \mu_B H \cdot S_{x,y,z} \right) + \ldots$$

contains three terms: the first describes intrachain exchange $J$ (x runs along crystal b axis), the second – uniform DM interaction $D_{y,z}$ between chain spins, and the third is the usual Zeeman term, allowing for anisotropic g-factor. The dots stand for the omitted interchain exchange as well as DM interactions on interchain bonds. Detailed symmetry analysis of the allowed DM interactions shows that there are four different orientations of the DM vector (see Fig. 6 in [4]) depending on chain’s integer coordinates $y,z$: $D_{y,z} = D_{x}(-1)^{y}a + D_{c}(-1)^{y}c$. Here $z$ indices magnetic b – c layers, while $y$ numerates chains within a layer. Crucially, crystal symmetry forbids DM vector to have component along the b axis [4].

The essence of the observed ESR line splitting can be explained by considering a single Heisenberg chain with uniform DM interaction with vector $\mathbf{D}$ along the local $\hat{z}$ axis, and $\mathbf{H} \parallel \hat{z}$ ($D_{y,z} \rightarrow D \hat{z}$, $\mathbf{H} \rightarrow H \hat{z}$). In this geometry the DM interaction can be gauged away by position-dependent rotation of lattice spins,

$$S_{x,y,z}^+ = S_{x,y,z}^+ e^{i\alpha x}, \quad S_{x,y,z}^- = S_{x,y,z}^- e^{i\alpha x}.$$  \hfill (3)

The rotation angle $\tan(\alpha) = -D/J$ is chosen so as to eliminate the DM coupling from the Hamiltonian. The transformed $\mathcal{H}$ describes spin chain with quadratic in $D$ easy-plane anisotropy. To linear in $D/J$ accuracy the ESR response of this model coincides with that of an isotropic Heisenberg chain, detailed study of which is described in Ref. [19]. ESR absorption is determined by the transverse structure factor $S_{2x}(\omega, \tilde{q}) = \delta(\omega, \tilde{q})$ of the chain, evaluated at $\tilde{q} = 0$. This is given by the sum of delta-function peaks at frequencies $2\pi\hbar\nu_{R/L} = |\nu D+/\pm D/2| [24]$. Note that the splitting $\pi D = (D^2 + D^2)^{1/2}$ is linear in $D$ which justifies our neglect of the easy-plane anisotropy.

While the four-sublattice structure of the DM vectors makes it impossible to study the $\mathbf{D} \parallel \mathbf{H}$ configuration in Cs$_2$CuCl$_4$, the above argument allows one to immediately understand polarization-dependent absorption (finding (iii) above) in zero magnetic field, at the frequency $2\pi\nu = \pi D/2\hbar$. Since the microwave absorption is proportional to the square of the microwave field component perpendicular to the effective field, we conclude that configuration with $\mathbf{h} \perp \mathbf{D}$ (that is, $\mathbf{h} \parallel \mathbf{b}$) should result in maximal possible absorption. For $\mathbf{h}$ along the a (c) axis, absorption is a factor $D^2/D^2$ ($D^2/D^2$) smaller. Using numerical estimates of $D_{a,c}$ derived below, the absorption for different polarizations should obey the relations: $P_b/P_a \simeq 1.6$ and $P_b/P_c \simeq 2.8$. This agrees qualitatively with our data presented in Fig. 4 – the zero-field absorption at $\nu = 14$ and 17 GHz is a factor of 3 more intensive for $\mathbf{h} \parallel \mathbf{b}$ than for $\mathbf{h} \parallel \mathbf{a,c}$. 

To understand our findings (i) and (ii), one needs to analyze the arbitrary orientation of the $\mathbf{H}$ and $\mathbf{D}$ vectors, which is the problem solved in Ref. [23]. The main physical point of [23] consists in the observation that a uniform DM interaction, much like a spin-orbit Rashba interaction in 2D conductors [14–16], acts on spinon excitations of 1D chains as an internal momentum-dependent magnetic field. Technically, this observation follows from spin-current formulation [24] of the problem [2], which is valid below the strong-coupling temperature scale $T_0 \sim J e^{-\pi S}$ ($S = 1/2$ for the spin chain here) [26]. The spin currents $\mathbf{M}_{R/L}$ represent spin density fluctuations of spinons near the right/left (R/L) Fermi points of a 1D system. It follows that the right and left-moving currents experience different, in magnitude and direction, total magnetic fields: $\mathbf{B}_R = \mathbf{H} + \hbar \mathbf{D}/g\mu_B J$ and
FIG. 5. (Color online). Spinon spectrum of S = 1/2 Heisenberg chain for \( q \sim 0 \) with (solid lines) and without (dashed lines) DM interaction. When \( D \parallel \mathbf{H} \), momentum is boosted by \( q = D/J a_0 \).

\[ B_L = \mathbf{H} - \hbar \nu D/g_\mu_B J. \]  

It is then natural that the ESR response of such a chain consists of two peaks at frequencies \( 2\pi\nu_R/L = g_\mu_B B_R/L \) [25].

For the \( \text{Cs}_2\text{CuCl}_4 \)-specific configuration of chain DM interactions and \( \mathbf{H} = (H_a, H_b, H_c) \) our analysis predicts

\[
(2\pi\nu_R)^2 = (g_\mu_B B_a/2)^2 + (g_\mu_B B_b - (-1)^2\pi D_a/2)^2,
\]

\[
(2\pi\nu_L)^2 = (g_\mu_B B_b/2)^2 + (g_\mu_B B_a - (-1)^y\pi D_a/2)^2 + (g_\mu_B B_c - (-1)^y\pi D_c/2)^2,
\]

These equations naturally explain the difference between \( \mathbf{H} \parallel a, c \) and \( \mathbf{H} \parallel b \) situations. For \( \mathbf{H} \parallel b \) the external and the internal DM field are mutually perpendicular and the vector sum \( \mathbf{H} \pm D \) has the same absolute value for both signs. One then finds single ESR frequency \( \nu_R = \nu_L \) of the form (1) where the “gap” is in fact an internal DM field, \( \Delta/(2\pi\hbar) = \sqrt{D_a^2 + D_c^2}/(4\hbar) \approx 14 \) GHz, using \( D_{a/c} \) values reported below. For \( \mathbf{H} \parallel a, c \) the DM field has a component along \( \mathbf{H} \) and the frequencies of the two spin excitations are different. Solving equations (11) at fixed frequency for the magnetic field \( \mathbf{H} \) within the \( a-b \) plane we were able to fit the experimental angular dependence in Fig. 4. In this way we obtained \( D_a/(4\hbar) = 8 \pm 2 \) and \( D_c/(4\hbar) = 11 \pm 2 \) GHz, which corresponds to 0.29 ± 0.07 and 0.39 ± 0.07 T. Details of the angular dependence of ESR for field oriented within \( a-c \) plane are discussed in Ref. 24.

A more detailed comparison between the experiment and the theory would require extending the latter to finite temperatures since the reported measurements are performed in the intermediate temperature range \( T_N = 0.02K < T < T_{CW} = 4K \). Temperature dependence of the gap \( \Delta \) for \( \mathbf{H} \parallel b \) in a wider range including \( T_N \) is shown in Fig. 11. The gap of the range in the gap 1 K < \( T < 2 K \) is much slower than right near \( T_N \). This supports our main assumption that the reported spectral features of \( \text{Cs}_2\text{CuCl}_4 \) reflect specific spin chain physics which dominates the temperature range \( T_N < T < T_{CW} \).

In conclusion, we demonstrated that the uniform DM interaction, which is a distinctive feature of \( \text{Cs}_2\text{CuCl}_4 \), results in a new kind of spin resonance in a \( S=1/2 \) chain antiferromagnet. The observed spectrum is a consequence of the splitting of the chain’s spinon continuum by the internal magnetic field which is produced by the uniform DM interaction. It would be interesting to probe this physics independently via polarized neutron scattering as suggested in Ref. 27. We believe that our findings can be extended to higher-dimensional magnetic systems with fractionalized spinon excitations.
