We investigate the discovery potential of semileptonic hyperon decays in terms of searches of new physics at teraelectronvolt scales. These decays are controlled by a small SU(3)-flavor breaking parameter that allows for systematic expansions and accurate predictions in terms of a reduced dependence on hadronic form factors. We find that muonic modes are very sensitive to non-standard scalar and tensor contributions and demonstrate that these could provide a powerful synergy with direct searches of new physics at the LHC.

Introduction. The meson and baryon semileptonic decays have played a crucial role in the discovery of the $V-A$ structure and quark-flavor mixing of the (charged current) electroweak interactions in the Standard Model (SM). From a modern perspective, high-precision measurements of these decays provide a benchmark to test the SM and complement the direct searches of new physics (NP) at teraelectronvolt (TeV) energies.

For example, the accurate determination of the elements $V_{us}$ and $V_{ub}$ of the Cabibbo-Kobayashi-Maskawa (CKM) matrix can be used to test its unitarity, constraining NP with characteristic scales as high as $\Lambda \sim 10$ TeV \cite{3}. Furthermore, one can test the $V-A$ structure of the charged currents in $d \to u$ transitions using neutron and nuclear $\beta$ decays \cite{3,9} and pion decays \cite{10,11}. Current limits for the associated NP scale are also at the TeV level, and important improvements are expected from future experiments \cite{12}. Searches of non-standard $d \to u$ transitions can also be done using LHC data, through e.g. the collision of $d$ and $u$ partons in the $pp \to e^{\pm} + MET + X$ channel (where MET stands for missing transverse energy) \cite{12}. This leads to an interesting synergy between low- and high-energy NP searches in these flavor-changing processes.

A similar comprehensive analysis of exotic effects in $s \to u$ transitions has not been done yet. The (semi)leptonic kaon decays are optimal laboratories for this study due to the intense program of high-precision measurements and accurate calculations of the relevant form factors that has been carried out over the last decades \cite{13}. Indeed, bounds on right-handed \cite{14,15} or scalar and tensor \cite{16} NP interactions at the $10^{-2} - 10^{-3}$ level (relative to the SM) can be obtained \cite{17,18}. Generally speaking, (pseudo)scalar and tensor operators modify the spectrum of the decay and a detailed knowledge of the $q^2$ dependence of the form factors becomes necessary \cite{19}.

In this letter we investigate the physics potential of the semileptonic hyperon decays (SHD) to search for NP. Although the description of these modes may seem involved due to the presence of six nonperturbative matrix elements or form factors, they present interesting features \cite{20-23}: (i) In the isospin limit, there are a total of 8 different channels, each having a differential decay rate with a rich angular distribution that could involve the polarizations of the baryons. (ii) The same form factors in different channels can be connected to each other and with other observables (e.g. electromagnetic form factors), (iii) in a model-independent fashion using the approximate SU(3)-flavor symmetry of QCD. (iii) The maximal momentum transfer is small compared to the baryon masses and it is parametrically controlled by the breaking of this symmetry. Therefore, a simultaneous SU(3)-breaking and “recoil” expansion can be performed that simplifies, systematically, the dependence of the decay rate on the form factors.

On the experimental side there is much room for improvement. Except for the measurements performed by the KTeV and NA-48 Collaborations in the $\Xi^0 \to \Sigma^+ \ell^- \nu$ channel \cite{24,28}, most of the SHD data is more than 30 years old \cite{29}. On the other hand, (polarized) hyperons could be produced abundantly in the NA62 experiment at CERN \cite{30} or in any other hadron collider like the future $p\bar{p}$ facility PANDA \cite{31} or in any other hadron collider like the future $p\bar{p}$ facility PANDA \cite{32}.

In the following, we investigate the physics reach of the SHD with a discussion based on the sensitivity of the total decay rates to non-standard scalar and tensor interactions. We show that the bounds from SHD are competitive with those derived from the LHC data on the $pp \to e^{\pm} + MET + X$ channel and leave the interplay with kaon decays for future work (see \cite{14,17} for the current status).

The SM effective field theory. In the SM, and at energies much lower than the electroweak symmetry breaking scale, $v = (\sqrt{2} G_F)^{-1/2} \approx 246$ GeV, all charged-current weak processes involving up and strange quarks are described by the Fermi ($V-A$) times ($V-A$) four-fermion interaction. Beyond the SM, the most general effective Lagrangian is \cite{3}:

\begin{equation}
\mathcal{L}_{\text{eff}} = -\frac{G_F V_{us}}{\sqrt{2}} \left( 1 + \epsilon_L + \epsilon_R \right) \times \\
\sum_{\ell=e,\mu} \left[ \bar{\ell} \gamma_\mu (1-\gamma_5) \nu_\ell \cdot \bar{u} \left[ \gamma^\mu - (1-2\epsilon_R) \gamma^\nu \gamma_5 \right] s \right. \\
+ \left. \bar{\ell} (1-\gamma_5) \nu_\ell \cdot \bar{u} \left[ \epsilon_S - \epsilon_F \gamma_5 \right] s \right] \\
+ \epsilon_T \bar{\ell} \sigma_{\mu\nu} (1-\gamma_5) \nu_\ell \cdot \bar{u} \sigma^{\mu\nu} (1-\gamma_5) s + \text{h.c.},
\end{equation}
neglecting $O(\ell^2)$ terms and derivative interactions, and where we use $\sigma^{\mu\nu} = [\gamma^\mu, \gamma^\nu]/2$. This Lagrangian has been constructed using only the SM fields relevant at low scales, $\mu \sim 1$ GeV, and demanding the operators to be color and electromagnetic singlets. Furthermore, we have restricted our attention to non-standard interactions that conserve lepton flavor and are lepton universal. Finally, we assume that the Wilson coefficients (WC) $\epsilon_i$ are real, since we focus on CP-even observables.

In light of the null results in direct searches of NP at colliders, we assume that its typical scale, $\Lambda$, is much larger than $\nu$. In such case, NP can be parameterized using an effective (non-renormalizable) Lagrangian, $\mathcal{L}_{\text{eff}} = \mathcal{L}_{\text{SM}} + (1/\Lambda^2) \sum_i \alpha_i \mathcal{O}_i^{(6)} + \ldots$, where the $\mathcal{O}_i^{(6)}$ are now operators built with all the SM fields and subject to the structures of its full (unbroken) gauge symmetry group [34]. The WC $\epsilon_i$ in eq. (1) are generated by the high-energy WC $\alpha_i$, which in turn can be obtained by matching to a particular NP model at $\mu = \Lambda$, and by running down to $\mu \sim 1$ GeV using the renormalization group equations, with the heavier fermions and weak bosons integrated out in the process [35–39].

This framework, usually referred to as the SM effective field theory (SMEFT), allows for a bottom-up investigation of NP, describing the implications of collider searches for low-energy experiments and vice versa. Needless to say, this interplay would become crucial in shaping the NP if a discrepancy with the SM is to be found. Examples of top-down applications, with correlated effects at high- and low-energies, can be found in scenarios with lepto-quarks [40] or extra scalar fields [6–19].

**Semileptonic hyperon decays.**- Neglecting electromagnetic corrections, the amplitude for a particular SHD $B_1(p_1) \to B_2(p_2) \ell^- (p_3) \bar{\nu}_\ell (p_4)$ factorizes into the leptonic and baryonic matrix elements. For the (axial)vector hadronic currents we have the parametrization in terms of the standard form factors [22]:

$$\langle B_2(p_2) | \bar{u}_\gamma \gamma_5 | B_1(p_1) \rangle = \bar{u}_2(p_2) \left[ f_1(q^2) \gamma_\mu + \frac{f_2(q^2)}{M_1} \sigma_{\mu\nu} q^{\nu} + \frac{f_3(q^2)}{M_1} q_\mu \right] u_1(p_1),$$

$$\langle B_2(p_2) | \bar{u}_\gamma \gamma_5 | B_1(p_1) \rangle = \bar{u}_2(p_2) \left[ g_1(q^2) \gamma_\mu + \frac{g_2(q^2)}{M_1} \sigma_{\mu\nu} q^{\nu} + \frac{g_3(q^2)}{M_1} q_\mu \right] \gamma_5 u_1(p_1),$$

whereas the non-standard (pseudo)scalar and tensor interactions introduce new form factors [41]:

$$\langle B_2(p_2) | \bar{u} | B_1(p_1) \rangle = f_S(q^2) \bar{u}_2(p_2) u_1(p_1),$$

$$\langle B_2(p_2) | \bar{u} \gamma_5 | B_1(p_1) \rangle = g_P(q^2) \bar{u}_2(p_2) \gamma_5 u_1(p_1),$$

$$\langle B_2(p_2) | \bar{u} \sigma_{\mu\nu} | B_1(p_1) \rangle \simeq f_T(q^2) \bar{u}_2(p_2) \sigma_{\mu\nu} u_1(p_1).$$

In eqs. (2–6), $u_{1,2}$ are the parent and daughter baryon spinor amplitudes, $M_{1,2}$ their respective masses, $q = p_1 - p_2$ is the momentum transfer, with $m_1^2 \leq q^2 \leq (M_1 - M_2)^2$. Furthermore, in Eq. 6 we have neglected other contributions to the matrix element of the tensor current since they are kinematically suppressed $\sim O(q/M_1)$ [41].

A crucial aspect in the study of the SHD is the approximate $SU(3)$-flavor symmetry of QCD. It controls the phase space of the decay and allows for a systematic expansion of the observables in the generic symmetry breaking parameter, $\delta = (M_1 - M_2)/M_1$ [21]. Relations among form factors are obtained in the exact symmetric limit using standard group theory (see e.g. Ref. [42]) and $O(\delta)$ corrections can be calculated using model independent methods [43–50]. In addition, the form factors can be expanded around $q^2 = 0$ in powers of $q^2/M_X^2 \sim \delta^2$, where $M_X \sim 1$ GeV is a hadronic scale related to the mass of the resonances coupling to the currents [51–52].

Let us illustrate this with the total decay rate for the electronic mode in the SM which, expanded up to next-to-leading order (NLO) in $\delta$ and neglecting $m_v$, is [21]:

$$\Gamma_{e, \text{SM}} \simeq \frac{G_F^2}{60 \pi^3} \frac{|V_{us}| f_1(0)|^2}{M_X^2} \Delta^5 \left[ \left( 1 - \frac{3}{2} \delta \right) \left( 1 - \frac{3}{2} \delta \right) \left( \frac{1 - 3 \delta}{2} \right) g_1(0)^2 - 4 \delta g_2(0) g_1(0) f_1(0) f_1(0) \right], \tag{7}$$

with $\Delta = M_1 - M_2$. This expression contains a minimal dependence on the form factors. No information on their $q^2$ dependence is required and, moreover, the last term can be neglected because the weak-electric charge, $g_2(0)$, is itself $O(\delta)$ [41]. Thus, besides $G_F$ and $V_{us}$, and up to a theoretical accuracy of $O(\delta^2) \sim 1 - 5\%$, the total decay rate of the electronic mode in the SM only depends on hyperon vector and axial charges, $f_1(0)$ and $g_1(0)$. Eq. 7 makes manifest that $f_1(0)$ is essential for extracting $V_{us}$ from the rates, while the ratio $g_1(0)/f_1(0)$ can be obtained measuring the angular distribution of the final lepton [21–22]. Neglected electromagnetic corrections are of a few percent [21–53], well within the accuracy achieved at NLO in the $SU(3)$ expansion.

Beyond the SM, we generally have two types of effects. On one hand, (axial)vector modifications to the SM, described by the WC $\epsilon_{\ell L,R}$, can be arranged (cf. Eq. 1) into a change of the normalization of the rate according to the replacement $V_{us} \to V_{us} = (1 + \epsilon_L + \epsilon_R) V_{us}$, and of the axial coupling to the leptonic current by the factor $(1 - 2\epsilon_R)$. The former combination involves a modification of $V_{us}$ which has been tightly constrained by testing CKM unitarity [3]. The latter could be determined in SHD from the measured $g_1(0) \to g_1(0) = (1 - 2\epsilon_R) g_1(0)$ only if $g_1(0)$ was known accurately from QCD (for recent progress in the lattice see Refs. [54–55]).

On the other hand, the WC $\epsilon_{S,P,T}$ introduce new structures in the energy and angular distributions. Restricting ourselves to $O(\ell^2/\Lambda^2)$ (or linear in the WC), they appear from the interference of the NP terms with the SM and the contributions of the (pseudo)scalar and tensor operators are suppressed by $m_v/\sqrt{q^2}$. Therefore, while the electronic channels can be analyzed specifically to measure and study the normalization of the rates $|V_{us} f_1(0)|$ and the relevant form factors, the muonic modes could use the information thus obtained to constrain
the (pseudo)scalar and tensor operators. Besides that, it is important to note that the pseudoscalar quark bilinear receives a kinematical $O(q/M_t)$ suppression that largely neutralizes the sensitivity of SHD to $\epsilon_P$ (see however Ref. [80]). For this reason, we center our discussion below on the study of $\epsilon_S$ and $\epsilon_T$.

We expand the contributions in the SM up to $O(\delta)$, but we keep only the leading terms in the NP terms. This implies a relative $O(\delta^2)$ error in the SM predictions, which we fix to a 5% in all channels for definiteness, and an uncertainty $O(\delta) = 10 - 20\%$ in the sensitivity to NP that will not affect the conclusions of our analysis.

**Bounds on scalar and tensor operators.** Let us now introduce the ratio:

$$R^{\mu e} = \frac{\Gamma(B_1 \to B_2 \mu^- \bar{\nu}_\mu)}{\Gamma(B_1 \to B_2 e^- \bar{\nu}_e)}.$$  \tag{8}

This observable is not only sensitive to lepton-universality violation but also linearly sensitive to $\epsilon_S$ and $\epsilon_T$. In addition, one expects the dependence on the form factors in the SM to simplify in the ratio. In fact, working at NLO we obtain:

$$R_{\text{SM}}^{\mu e} = \sqrt{1 - \frac{m_{\mu}^2}{\Lambda^2}} \left( 1 - \frac{9}{2} \frac{m_{\mu}^2}{\Delta^2} - 4 \frac{m_{Q}^4}{\Delta^4} \right) + 15 \frac{m_{\mu}^4}{2 \Delta^2} \text{arctanh} \left( \sqrt{1 - \frac{m_{\mu}^2}{\Delta^2}} \right).$$  \tag{9}

This is a remarkable result: up to a relative theoretical accuracy of $O(\delta^2)$, $R^{\mu e}$ in the SM does not depend on any form factor. In Table I we compare the experimental ratios to the results predicted in the SM. As discussed above, the main reason for the large experimental errors is that most of the data in the muonic channel is very old and scarce. At this level of precision, which generously covers the theoretical accuracy attained by Eq. (9), we observe that the experimental data on $R^{\mu e}$ agrees with the SM.

One can now use this consistency of the data with the SM to set bounds on the WC of the scalar and tensor operators, which generate the following non-standard contribution:

$$R_{\text{NP}}^{\mu e} \simeq \frac{(\epsilon_S f_S(0)/f_1(0) + 12 \epsilon_T f_T(0)/f_1(0))}{(1 - \frac{3}{2} \delta)} \left( 1 + 3 \frac{g_1(0)^2}{f_1(0)^2} \right) \Pi(\Delta, m_{\mu}),$$  \tag{10}

where $\Pi(\Delta, m_{\mu})$ is a phase-space integral:

$$\Pi(\Delta, m_{\mu}) = \frac{5}{2} m_{\mu}^2 \left[ \left( 2 + 13 \frac{m_{\mu}^2}{\Delta^2} \right) \sqrt{1 - \frac{m_{\mu}^2}{\Delta^2}} - 3 \left( 4 \frac{m_{\mu}^2}{\Delta^2} + \frac{m_{Q}^4}{\Delta^4} \right) \arctanh \left( \sqrt{1 - \frac{m_{\mu}^2}{\Delta^2}} \right) \right].$$  \tag{11}

It is particularly convenient to express the dependence on the WC in “units” of the SM ratio:

$$\frac{R^{\mu e}}{R_{\text{SM}}^{\mu e}} = 1 + r_S \epsilon_S + r_T \epsilon_T,$$  \tag{12}

where $r_{S,T}$ are dimensionless numbers encapsulating the net sensitivity to the WC.

**Table I:** Comparison between the predictions of $R^{\mu e}$ in the SM at NLO and experimental measurements for different SHD.

| Process | Expt. | SM-NLO |
|---------|-------|--------|
| $\Lambda \to p$ | $0.189(41) \ 0.442(39) \ 0.0092(14) \ 0.6(5)$ | $0.153(8) \ 0.444(22) \ 0.0084(4) \ 0.275(14)$ |

**Table II:** SHD data for $g_1(0)/f_1(0)$ and theoretical determinations of $f_S,T(0)/f_1(0)$ at $\mu = 2$ GeV used in this work. The corresponding $r_{S,T}$ are shown in the last two lines.

| Process | Expt. | SM-NLO |
|---------|-------|--------|
| $\Lambda \to p$ | $g_1(0)/f_1(0) = 0.718(15) \ -0.340(17) \ 1.210(50) \ 0.250(50)$ | $f_S(0)/f_1(0) = 1.90(10) \ 2.80(14) \ 1.36(7) \ 2.25(11)$ |

The values of the form factors that we use to calculate $r_{S,T}$ are given in Tab. II. The ratio $g_1(0)/f_1(0)$ is measured from the angular distribution of the electronic channels [29]. The scalar form factor can be obtained, up to electromagnetic corrections, using the conservation of vector current in QCD, $f_S(0)/f_1(0) = \Delta/(m_{Q} - m_{\mu})$ [9]. For the tensor form factors we use model calculations [56], whose errors are difficult to quantify. Nevertheless, it is interesting to note that the tensor form factor for the neutron $\beta$-decay is predicted to be 1.22, which is in the ballpark of the values obtained in the lattice [6] [55] [57] [59]. This situation should be easily improved by future lattice calculations of the hyperon decay tensor charges.

The sensitivities to $\epsilon_S$, $\epsilon_T$ exhibited by the SHD (last two lines of Tab. II) are strongly channel-dependent. In Fig. 1 we show 90% confidence level contours in the $(\epsilon_S, \epsilon_T)$ plane using a $\chi^2$ that includes the experimental measurements of $R^{\mu e}$ and where we propagate the experimental and theoretical uncertainties of the SM predictions in quadratures. For $r_{S,T}$ we use the values in Tab. II. As we can see, even though the experimental data on $R^{\mu e}$ is not precise, the strong sensitivity of SHD to NP leads to stringent bounds in $\epsilon_{S,T}$; namely:

$$\epsilon_S = 0.003(40), \quad \epsilon_T = 0.017(34),$$  \tag{13}

at 90% C.L. Accounting for the running of $\epsilon_{S,T}$ on the renormalization scale $\mu$ [60], and assuming natural values for the WC at $\mu = \Lambda$, these bounds translate into $\Lambda \sim v(V_{us} \epsilon_{S,T})^{-1/2} \sim 2 - 4$ TeV [12].
also need to consider possible cancellations with linear effects in the future collider searches of NP in this channel, one might whereas in SHD is linear. Besides reducing the sensitivity of the cross section (14) on the WC is quadratic, affecting SHD measurements could have with LHC searches of NP affecting the muonic modes, on the other hand, show a strong linear sensitivity to scalar and tensor contributions that depend on the different combinations of form factors in each channel. This allows to constrain them using SHD alone, with a precision that is competitive with the LHC data, cf. Fig. 1 and Eq. (13).

Our hope is that the present study triggers a program of high-precision measurements of different observables in the SHD. Hyperons can be produced in great numbers in current [30-32] and future facilities [31]. One may also wonder if better measurements could be extracted from the analysis of the data collected in past experiments like HyperCP [64], KTeV and NA48. Any development on the experimental side will directly improve the bounds on NP obtained in this work with an observable as simple as $R^{\mu\mu}$, and using data with $\sim 10-20\%$ relative errors.

Future improvements on the experimental precision will need to be accompanied by similar efforts on the theory side. In particular, the inclusion of $O(\delta^2)$ terms in the SM predictions would improve the accuracy to $\sim 1\%-1\%$. Besides that, further nonperturbative calculations of the tensor form factors would improve the assessment of the sensitivity to $\epsilon_T$. Finally, it will be important to perform this comprehensive analysis of the SHD in complementarity with the kaon decays. Work along these lines is in progress.

**Acknowledgements.** We thank Sacha Davidson and Elizabeth Jenkins for useful discussions. The project was partially funded by DOE grant de-sc0009919 (H.-M.C.), the Lyon Institute of Origins, grant ANR-10-LABX-66 (M.G.A), the People Programme (Marie Curie Actions) of the European Union’s Seventh Framework Programme (FP7/2007-2013) under REA grant agreement PIOF-GA-2012-330458 (J.M.C.) and the Spanish Ministerio de Economía y Competitividad and European FEDER funds under the contract FIS2011-28853-C02-01 (J.M.C.).
