Abstract

Colletotrichum cereale is an ascomycete inhabitant of cool-season Pooideae grasses. The fungus has increased in frequency over the past decade as a destructive pathogen of Poa annua and Agrostis stolonifera turfgrass. Colletotrichum cereale exists as two lineages, designated clades A and B, but little is known about the distribution of these clades in natural environments, or what role these subdivisions may play in the trajectory of disease outbreaks. In this study, our objective was to determine the frequency of C. cereale clades A and B. To rapidly discriminate between the two C. cereale clades, a real-time PCR assay was developed based on the Apn2 gene. A collection of 700 C. cereale pathogens and endophytes from twenty Pooideae grass genera were genotyped. 87% of the collection was identified as part of clade A, 11.7% as part of clade B, and 1.3% was a mixture. Colletotrichum cereale from turfgrass hosts in North America were most commonly members of clade A (78%). The overabundance of clade A in turfgrass isolates was directly attributable to the dominance of this lineage from southern sampling sites, irrespective of host. In contrast, 111 C. cereale turfgrass isolates collected from northern sampling sites were evenly distributed between clades A and B. Only 28% of C. cereale from A. stolonifera at northern sampling sites were part of clade A. These data show that environmental factors such as geographic location and host identity likely played a role in the distribution of the major C. cereale clades in North American turfgrass.

Introduction

Colletotrichum cereale is a widely distributed fungus that lives in association with monocot grasses of the Poaceae family [1], [2]. The fungus inhabits at least twenty cool-season (C3 photosynthesis) Pooideae genera in numerous ecosystems, including cultivated cereal crops, grasses grown for forage, athletic fields and lawns, and natural landscapes such as prairies and grasslands [3],[4]. Although best known as a pathogen of cultivated grasses, C. cereale also survives in host tissue without producing any visible signs of disease [2]. C. cereale causes anthracnose disease in parasitized grasses, with symptoms varying based on the host and tissue infected [3]. Since the initial description of the fungus in 1908, sporadic but notable disease outbreaks caused by C. cereale have been documented [3]. Production of wheat, oats and barley in the United States suffered from severe anthracnose outbreaks during the early part of the 20th century [3]. More recently, grasses cultivated as turfgrass on golf course putting greens have been plagued by destructive anthracnose disease outbreaks, resulting in substantial economic losses and an undesirable but requisite increase in fungicide usage [5]. In turfgrass systems, anthracnose caused by C. cereale manifests as either a foliar blight of senescing tissue or a basal stem rot, characterized by blackened, rotted, water-soaked tissue at the base of the plant that eventually leads to host death. Two turfgrass species are primarily affected by anthracnose disease: Poa annua and Agrostis stolonifera [3].

The emergence of C. cereale as one of the primary diseases impacting turfgrass health on golf course putting greens has prompted several investigations in recent years pertaining to the identity of the fungus, the structure of populations, and the management factors that influence the development of disease in turfgrass hosts (e.g. [6–16]). For most of the 20th century, C. cereale was considered conspecific with C. graminicola, the fungus responsible for maize anthracnose disease, based on morphological similarities [17]. Multi-locus phylogenetic trees established the uniqueness of C. cereale [6], and confirmed the utility of hyphal appressoria as a distinguishing character for C. graminicola [18]. Subsequent work showed that C. cereale was the basal taxon in a diverse clade of Colletotrichum species associated with grasses of the Poaceae family [2], [9], [19]. This assemblage of grass-associated species is collectively referred to as the “graminicola” species aggregate, named after the most prominent member, C. graminicola [20]. The graminicola aggregate is populated by at least seventeen species, most of which are limited to just one or a few host species, and infect warm-season (C4 physiology) grasses [2], [21–23]. C. cereale stands out within the graminicola aggregate for two reasons: (1) this species is the only known member of the group that infects cool-season grasses; and (2) it is plurivorous, with fourteen genera documented as hosts [4].
The wide-host range of *C. cereale* is misleading, as multi-locus sequence analysis shows that the species is subdivided into eleven populations structured according to host/ecosystem origin [2]. The *C. cereale* populations are distributed across two major lineages, designated clade A and clade B [2], [6–9]. *C. cereale* clades A and B exhibit an overlapping host range. Both clades are responsible for anthracnose disease in turfgrass, and have also been associated with Pooid grasses as endophytes [2]. Despite substantial evidence for lineage diversification, significant levels of gene flow link clades A and B, indicating that they are of a single species [6–8]. Clade A is subdivided into ten subpopulations, each corresponding with a single host (*P. annua* or *A. stolonifera*) or ecosystem (turfgrass, cereal crops, or prairie) [2]. In contrast, clade B is an exceptionally diverse assemblage of isolates from varied environments and hosts, with no subgroups documented [2].

While the subdivision of clade A into subpopulations appears to be driven by host specialization, the factors shaping the earlier diversification of *C. cereale* into clade A and clade B are unknown. Clade A has traditionally been found in higher numbers and encompassing a larger geographic area than clade B isolates [2], [6], [8]. However, this pattern may reflect a bias in sampling rather than structure of natural populations. In this study, our objective was to evaluate a large sample of *C. cereale* isolates to determine the frequency and distribution of clade A and clade B from natural populations, before and after the major turfgrass anthracnose disease outbreaks.

**Materials and Methods**

*Colletotrichum cereale* and other fungal samples

Table S1 summarizes the 700 *Colletotrichum cereale* samples included in the present study. The *C. cereale* samples were derived from four sources: (a) 575 samples were isolates of *C. cereale* established in axenic culture, either new or previously described [2], [6–9]; (b) 87 samples were preserved *C. cereale* fungarium specimens consisting of plant tissue colonized by *Colletotrichum* fungi, as diagnosed through the presence of setae; (c) 17 samples were annual bluegrass (*Poa annua*) plants symptomatic for anthracnose disease and showing visible signs of *C. cereale* (setae); and (d) 21 samples were wheat plants (*Triticum aestivum*) asymptomatic for anthracnose disease, but with *C. cereale* setae present on sampled tissue. All wild grown grasses were identified through examination of vegetative features and inflorescences using standard morphological keys for grasses [24]. Species of cultivated cereals and grasses were identified by color, leaf, and visible inflorescence characteristics. Herbarium materials were identified to host following the original collector identifications and confirmed through morphological examinations using the Hitchcock key.

Thirty-four of the cultured isolates were selected to serve as biological replicates. All biological replicates consisted of separate cultures of a given isolate, from which a separate DNA extraction was performed. Ten samples of non-target fungi grown in pure culture were also included as negative controls, along with eight samples of plant tissue (*Viola* sp. and *Poa pratensis*) and two fungarium specimens where *Colletotrichum* was present on dicot hosts (*Cucumis longa*, *Malva rotundifolia*) but for which the species *C. cereale* was not expected.

**DNA extraction and real-time PCR**

Genomic DNA from cultured fungal isolates was extracted using a standard phenol:chloroform protocol as previously described [25]. Genomic DNA from fungarium specimens and grass tissue colonized by *C. cereale* was extracted by excising small sections of plant tissue where the fungus was evident (~5–10 cm²), placing the tissue in a 2 ml microcentrifuge tube containing six 2.5 mm glass beads (BioSpec Products, Bartlesville, OK), and shaking in a BioSpec bead-beater (BioSpec Products) on the medium setting for six minutes.

DNA was extracted from the lysed tissue using the Omni Prep DNA Extraction Kit (G-Biosciences, Maryland Heights, MO) according to the manufacturer’s protocol; final quantities were assessed using a NanoDrop 1000 spectrophotometer (Thermo Scientific, Wilmington, DE).

Target regions for primers and hydrolysis probes for real-time PCR were designed from an alignment of the 750-bp region of the *Apn2* sequencing marker as a template [2]. Primer3 was used to identify optimal sites based on target site DNA properties ([http://frodo.wi.mit.edu/primer3/](http://frodo.wi.mit.edu/primer3/)). Two probes, A-Apn2 and B-Apn2, were designed to fall within an 85 or 103 bp PCR amplicon to detect *C. cereale* clade A and clade B isolates, respectively. The two probes differed from one another by 8-bp within the 33-bp probe target site (Fig. 1). The forward primer A-Apn2-F contained one single nucleotide polymorphism (SNP) specific to clade A isolates, and the forward primer B-Apn2-F contained two SNPs specific to clade B isolates. The reverse primer, *A*-Apn2-R, was designed for universal use with both forward primers. Primers and probes were synthesized by Integrated DNA Technologies (Coralville, IA); the sequences are summarized in Table 1. Oligonucleotides synthesized for use as probes were modified on the 5’ end with the fluorescent reporter dye 6-carboxy-fluorescein (FAM) and on the 3’ end with the fluorescent quencher dye Iowa Black (IaBk).

An additional internal quencher, ZEN, was positioned in the center of both probes to enhance specificity. DNA stocks from cultured *C. cereale* samples were normalized for use in real-time PCR to 15 ng/µl and DNA extracted from leaf tissue colonized by *C. cereale* were diluted 1:50.

The majority of experiments were performed using the Step One Plus system (Applied Biosystems, Foster City, CA); the Roche Light Cycler 480 (Roche Applied Science, Indianapolis, IN) was used for part of the sample. Experiments were performed in 96 well plates: (a) Step One Plus system: MicroAmp Fast Optical 96-Well Reaction Plate (Applied Biosystems); (b) LightCycler 480 White Multiwell Plate 96 (Roche). Reactions consisted of 20-µl volumes containing the following: 2 µl of sample DNA, 1.25 µl of each primer (20 µM stocks), 2.5 µl probe (2 µM stocks), 10 µl Roche Light Cycler 480 Probes Master Mix, and PCR-grade sterile dH2O provided with the master mix to volume. The cycling program was as follows: 95°C for 120 s, followed by 45 cycles of 95°C for 5 s, 60°C anneal for 30 s, and 72°C extension for 1 s. All reactions were performed a minimum of three times for all samples.

DNA from *C. cereale* isolates from which the *Apn2* marker was sequenced was performed by real-time PCR, and at least one positive control was included with each 96-well plate analyzed. Water blanks were included as negative controls for all plates, and non-target DNA from other fungal species was also tested (Table S2). Positive reactions were scored as those that reached the threshold value prior to cycle 40. Amplification was confirmed for all samples by agarose gel electrophoresis after cycling. Probes were considered specific to *C. cereale* clades if cycle threshold (CT) values were zero for non-target DNA and water controls.

Assay sensitivity was assessed by evaluating two 10-fold dilution curves of genomic DNA extracted from pure cultures of *C. cereale* clade A isolate ANCG 17–15 and *C. cereale* clade B isolate NJ-4990 (Fig 2). Reactions were run on the SmartCycler II (Cepheid, Sunnyvale, CA) using 2.5 µl of each primer (10 µM stocks), 2.5 µl probe (1 µM stock), 5 µl PCR grade water, and Cepheid’s
Smartmix HM lyophilized PCR master mix. Concentrations ranged from 0.4 pg/μl to 100 ng/μl. Standard curves were generated from the dilutions series data to calculate reaction efficiencies and determine minimum detection levels.

**Statistical Analyses**

An exact binomial logistic regression model was fit to the clade distribution data using the logistics procedure in Statistical Analysis System software v. 9.3 (SAS Institute, Cary, NC). The model tested for the effects of region, host species, and the interaction of region and host on clade distribution.

**Results**

**Analysis of DNA from cultured *Colletotrichum cereale* isolates**

Dual-labeled hydrolysis probes and primer pairs were designed using an *Apn2* nucleotide sequence alignment as a template to identify fixed nucleotide sites that discriminated between the two major *C. cereale* subgroups responsible for anthracnose disease, clades A and B [6]. The lowest level of DNA detection was 4.0 × 10^-4 pg and 5.0 × 10^-3 pg, for *C. cereale* clade A and clade B, respectively (Fig. 2). Reaction efficiencies were 99.53% (amplification factor = 2) for the clade A assay and 147.74% (amplification factor = 2.48) for the clade B assay.

A sample of 575 cultured isolates of *C. cereale* collected from 20 species of pooid grasses was screened using the *Apn2* real-time PCR assays. 96% of the cultured isolates originated from North America, with 98% of the isolates collected 1998 or later. Data from these reactions are summarized in Table 2 and Table S1. Real-time PCR amplification plots of the *Apn2* probes used to screen a 96-well plate of *C. cereale* infected samples is available in Figure 3. Diagnosis for the 34 samples used as biological replicates yielded the same diagnosis for all replicates (Table S3). Negative controls, water controls and non-target samples produced CT values equal to zero.

88% of the cultured *C. cereale* isolates were diagnosed as members of clade A, based on positive calls made using the A- *Apn2* assay (avg. CT = 27.57) and negative calls made using the B- *Apn2* assay. Twelve percent of the cultured *C. cereale* isolates were diagnosed as members of clade B, based on positive calls made using the B- *Apn2* assay (avg. CT = 27.59) and negative calls using the A- *Apn2* assay. Analysis of *C. cereale* isolate PA-5018-3, previously shown to possess mixed group A/group B RFLP fingerprints [8], produced a positive diagnosis from both the A- *Apn2* and B- *Apn2* assays (CT = 25.92 and 24.99, respectively), consistent with the known molecular type for this isolate. From the

700 samples were evaluated, plus ten additional non-target *Colletotrichum* and other species included as negative controls. Second derivative \(C_t\) (cycle threshold) values represent positive samples when the fluorescent signal crosses the amplification threshold prior to cycle 40. Average \(C_t\) values are based on a minimum of three technical replicates.

*The 35 biological replicates are not included in the count of positive reactions. Average \(C_t\) values are given as the mean \(C_t\) generated from all technical and biological replicates. Low fluorescence intensity and late \(C_t\) values (\(>40.0\)) were observed for these samples when tested using the B-Apn2 assay.*

doi:10.1371/journal.pone.0097706.t002
isolates. Six fungarium specimens were diagnosed as likely belonging to clade A after visual inspection of the amplification curves, as low fluorescence intensity and late C_T values were observed for these samples when tested against the B-Apn2 assay. Eight fungarium samples produced positive C_T values from both the clade A and clade B assays. Sequence analysis of the resultant amplicon revealed the presence of both the clade A and clade B genotype in these samples (data not shown). The remaining ten fungarium samples identified as C. cereale produced no C_T values for either clade A or B, as did the non-target species Colletotrichum coghnic (BPI 397265) and Colletotrichum sp. (BPI 397277). Visualization of the real-time PCR product through agarose gel electrophoresis and the amplification product of PCR reactions performed using primers alone on the negative fungarium samples yielded no detectable amplicons.

Sample-wide frequency of C. cereale subspecific groups

Of the 700 C. cereale samples, 98.4% were diagnosed using the A-Apn2 and B-Apn2 real-time PCR assays. All but one of the eleven undiagnosed samples were fungarium specimens. Of the 689 C. cereale with a group diagnosis, 87% of the sample was part of clade A, 11.7% was part of clade B, and 1.3% of the sample produced mixed A/B diagnoses (Table 2).

Table 3 summarizes C. cereale membership relative to host origin as diagnosed using the Apn2 real-time assays. Overall, C. cereale clade A samples were observed from all 32 Pooid host species (Table 3). In contrast, C. cereale clade B samples were only observed from eight of the Pooid genera.

98% of the C. cereale samples in this study originated from within North America. Of the sixteen samples from other geographic locales (Japan, Germany, Australia), all were cultured isolates. Only two C. cereale samples from outside North America, CBS 303.69 and CBS 304.69 collected from Agrostis tenuis and Anmophila arenaria, respectively, in Germany during 1967, were diagnosed by the Apn2 real-time assay as members of clade B. This diagnosis was consistent with previous nucleotide sequence data for these isolates [2].

The largest component of the C. cereale sample was drawn from cultured isolates of the fungus from the two primary economic hosts in North America – the turfgrasses Agrostis stolonifera and Poa annua (n = 78 and n = 191, respectively). Table 4 summarizes the distribution of C. cereale from these two hosts in North American samples. The 269 C. cereale samples from turfgrass hosts were plant pathogenic isolates, collected from diseased putting greens between 1998 and 2006, after the emergence of the destructive anthracnose disease outbreaks that took place beginning in the mid 1990s [5]. When this collection of C. cereale turfgrass isolates was typed using the Apn2 assays, the overall ratio of clade A to clade B isolates was 3.6 to 1 (A = 210; B = 59). 87% of all P. annua isolates were typed as members of clade A. In contrast, only 56% of the C. cereale isolates from A. stolonifera hosts were typed as members of clade A.

The dataset of North American turfgrass isolates of C. cereale was evaluated according to two broad geographic subdivisions – designated north and south, according to average annual minimum temperature extremes (Table 4). Analysis of clade A and clade B frequencies in these two broadly defined geographic regions showed that the overabundance of clade A isolates across the entire sample from turfgrass hosts was attributable to the C. cereale subsample from the southern region. The 158 C. cereale isolates collected from southern sites were predominantly members of clade A; only 2.5% of southern isolates were members of C. cereale clade B. In contrast, the 111 C. cereale isolates sampled from northern sites were almost evenly divided between clade A and group clade B. However, the frequency of the two C. cereale subgroups differed between isolates made from A. stolonifera and P. annua. Northern region isolates of C. cereale made from A. stolonifera (n = 46) were most commonly members of clade B by a factor of 2.4 to 1, whereas isolates made from P. annua (n = 65) were most commonly members of clade A by a factor of 1.6 to 1.

A clade × region interaction was detected using logistic regression analysis (Table 5). In the southern region of North America, no differences in sampling response were detected among hosts (p = 0.7%); there was a 98.9% and 97.6% probability of obtaining a clade A isolate when sampling from A. stolonifera or P. annua, respectively. However, when sampling in the northern region, there was a 28.3% probability of obtaining a clade A isolate from A. stolonifera, whereas there was a 66.1% chance of obtaining a clade A isolate when sampling from P. annua turf.

Discussion

The primary objective of this study was to examine the frequency of C. cereale clades A and B in the natural environment from a large sample of modern and historical specimens from North America. Our results show that clade A is the predominant group in natural populations of C. cereale. Furthermore, the frequency with which we observed clade A from historical specimens indicates that clade A has been the dominant C. cereale group in North America for at least a century. Despite the abundance of C. cereale clade A in the environment, clade B isolates were also identified throughout the entire sample, as part of both modern collections and from cereal crops and grasses dating back to the original 1908 C. cereale fungarium specimens. Thus, on the recent time scale, both lineages are endemic to North America, with direct evidence from fungarium specimens documenting their presence in the United States for over a century. This finding is consistent with the high levels of diversity observed for both C. cereale clades from previous multi-locus haplotype analysis [2].

Colletotrichum cereale isolates diagnosed as clade A dominated the overall collection screened in this study, comprising 87% of our samples. When the distribution of clades was evaluated based on host origin, we observed a similar trend for all non-turfgrass C. cereale isolates, with clade A outnumbering clade B on all non-turfgrass hosts. Of particular note was the broad host range of C. cereale clade A, with isolates from this lineage identified from 32 different Pooid grass species. In contrast, C. cereale clade B was only identified from eight Pooid species. On Agrostis, Agropyron, Anmophila, Anthoxanthum, Avenopus, Festuca, Holcus, Hordeum, Phleum, and Polygpon hosts, the dominance of clade A could be a result of limited sampling on these hosts, as each host was only represented by one to four samples. Still, the number of clade A isolates on the remaining hosts greatly outnumbers clade B and should not be discounted. Previous haplotype analysis suggests clade A may be the ancestral group for C. cereale [6], and the low frequencies and reduced host range from which we observed clade B isolates supports this theory. While additional data is need to confirm the haplotypes present in our sample collection, it is possible that clade B is transitioning to a broader host range.

The overabundance of clade A observed from the overall C. cereale collection did not hold true for isolates obtained from turfgrass hosts [A. stolonifera, P. annua] when the samples were subdivided based on host origin and broad geographic range. In southern regions of North America, clade A turfgrass isolates accounted for 97.5% of the sample, regardless of the host. In contrast, in northern regions, C. cereale clade A and clade B isolates from turfgrass were found in equal numbers. However, closer examination of the northern C. cereale isolates showed that the

*Triticum* species = *T. aestivum* and *T. vulgare*.

doi:10.1371/journal.pone.0097706.t003

The distinct frequencies observed from *C. cereale* clade A and clade B turfgrass isolates based on geographic region is an interesting finding, and rigorous fine-scale sampling should be conducted to confirm this theory. Regardless, we cannot ignore that this apparent geographic distribution may also be influenced by temperature and attributed at least in part to the environmental adaptations of the host. *P. annua* does not tolerate heat stress well [26], therefore it may serve as an opportunistic host for *C. cereale* clade A isolates in southern regions where the host is exposed to significant environmental stresses and weakened prior to infection. The optimum temperature for growth of *C. cereale* in culture and on detached leaf assays has been reported to be anywhere between 22°C to 28°C [27–31], whereas optimal infection in the greenhouse has been reported between 15°C–30°C [27], 27°C–33°C [32], and 30°C–33°C [33]. To date, a consensus temperature optima for *C. cereale* has not been determined, likely due to difficulties in establishing a repeatable, greenhouse-based inoculation protocol [5] but also possibly because differences in temperature optima for the two clades were not assessed in previous studies. Varying temperature preferences between *C. cereale* lineages could explain the difficulties surrounding the development of an inoculation protocol, and the range of temperatures reported from early studies, and should be investigated. While temperature extremes seem to play an important role in the *C. cereale* pathosystem, we cannot rule out that other factors in the regions, such as soil type and weather events, may be impacting pathogen distribution. Fine-scale, rigorous sampling is needed to further examine these factors.

Our data shows that clade A and B can co-exist together, as mixed infections on individual plants, or on closely situated plants comprising a single stand of grass. Nine samples derived from a single lesion possessed mixed A/B genotypes. Likewise, of the sixteen samples taken from a single *P. annua* research putting green, ten samples were diagnosed as members of clade A and six...
samples as clade B. On golf course putting greens, *P. annua* is best known for its ability to colonize established *A. stolonifera* stands, resulting in putting greens of mixed host composition. Given the ability of both clades to exist together in a single putting green, combined with our finding that clades A and B seem to exhibit a host preference in northern regions, golf course putting greens comprised of both *A. stolonifera* and *P. annua* may provide a unique host environment for *C. cereale*. This habitat may allow both clades of the fungus to come in frequent, close contact with one another, potentially resulting in new, aggressive strains of the fungus.

The presence of both major *C. cereale* clades in close proximity to one another – either on the same plant, or within a single stand of grass – raises interesting questions about the interactions between these two lineages, the mechanisms involved in sustaining gene flow while at the same time maintaining the distinction between lineages [2]. The sexual cycle for *C. cereale* has never been

### Table 4. Summary of the diagnosis of *Colletotrichum cereale* subgroups by geographic locale using the Apn2 real-time detection assays, A-Apn2 and B-Apn2.

Diagnoses are given for isolates of *C. cereale* made from diseased turfgrass hosts *Agrostis stolonifera* and *Poa annua*. Diagnoses are separated according to the geographic locale where the sample originated, broken down by states in the United States of America and provinces in Canada. States/provinces are subdivided into regions according to minimum extreme temperature of location following the USDA-ARS Plant Hardiness Zones. Southern region sampling sites were defined as those sites that fell within USDA-ARS Plant Hardiness Zones 7a to 9a (minimum extreme temperature range –17.8 to –15°C and –6.7 to –3.9°C, respectively). Northern region sample sites were defined as those sites that fell within USDA-ARS Plant Hardiness Zones 6a or colder (minimum extreme temperature range –23.3 to –20.5°C or less). Biological replicates and negative controls are not included. Dashes indicate that no samples originating from a given host plant were evaluated.

### Table 5. Exact logistic regression results on the probability of samples diagnosed as *Colletotrichum cereale* clade A across regions and turfgrass hosts.

| Region     | Host Plant          | Logit   | Odds    | Probability | P Value |
|------------|---------------------|---------|---------|-------------|---------|
| **Southern region** | *Agrostis stolonifera* | 3.4337  | 30.9911 | 0.9687      | 0.7916  |
|            | *Poa annua*         | 3.7136  | 41.0012 | 0.9762      | 0.7916  |
| **Northern region** | *Agrostis stolonifera* | –0.9316 | 0.3939  | 0.2826      | <0.0001 |
|            | *Poa annua*          | 0.6702  | 1.9546  | 0.6615      | <0.0001 |

doi:10.1371/journal.pone.0097706.t005
documented [3], yet gene flow is known to have occurred between clades A and B, and between several populations of this species [2, 6–9]. Several other Colletotrichum species (e.g. C. acutatum, C. lindenuthianum) are known to complete a parasexual cycle that creates diversity and yields new, pathogenic fungal races [34, 35], thus it is possible that C. cereale clade A and B isolates may be undergoing a similar process. This would provide a unique evolutionary advantage to pathogenic C. cereale isolates, particularly in heavily managed golf course putting greens, where fungicide resistant strains of C. cereale are emerging [36–39].

In the current study, we have developed an important assay for the rapid and accurate genotyping of C. cereale clades A and B, without the need for time consuming and labor intensive culturing. The biallelic fixation of the targeted A-Apn2 and B-Apn2 probe site for over 100 years demonstrates that utility of Apn2 as a diagnostic marker for C. cereale lineages. This assay provides an accurate, lineage specific identification of C. cereale in as little as 45 minutes from DNA extracted directly from infected host tissue. The assay is quantitative, and sensitive enough to detect as little as 4 pg of C. cereale DNA from heterogeneous mixtures of host and environmental DNA. This sensitivity and rapid diagnosis is in stark contrast to traditional culturing methods that require surface sterilizations and multiple sub-culturing steps on antibiotic media to eliminate contaminating organisms before yielding a pure culture. From an applied standpoint, this assay could be utilized for clinical diagnoses, to assess pathogen levels from golf course greens, to ensure that seed is pathogen-free, or as an experimental tool to confirm the identity of C. cereale clades. For C. cereale, we can now use this assay to look at the distribution of clades A and B within a single putting green and to monitor this distribution over time to gain insight about the trajectory of recent anthracnose disease outbreaks in turfgrass.

To our knowledge, this study also marks the first application of real-time PCR experiments for the detection of Colletotrichum species from preserved fungarium specimens. The Apn2 real-time PCR assays were able to reproducibly detect C. cereale from small portions of fungarium materials ranging in age from 70 to 120 years old with a high level of success. Previous work with Colletotrichum pathogens of warm season grasses – C. sublinola, C. echinochloae, and C. caudatum – has demonstrated the power of DNA-sequence based approaches to accurately genotype type specimens from fungarium materials >100 years old [21], [23]. Our experiments demonstrate the utility and sensitivity of real-time PCR as a tool to conduct molecular examinations of historical fungal collections for other Colletotrichum species. Real-time PCR assays are particularly well suited for fungarium specimens, as they rely on amplification of very short regions of DNA. Since post-mortem degradation and shearing of DNA into fragments <500-bp is ubiquitous in historic specimens [39], real-time PCR is well suited to the requirements of working with fungarium materials. The development of similar assays for other Colletotrichum species where species concepts are currently in a state of flux [20], may prove useful for typification, species delineation, and the examination of temporal changes in these organisms.

Supporting Information

Table S1 Cultured Samples of Colletotrichum cereale tested to determine clade membership (A or B) using real-time PCR assays. CT = cycle threshold. *Isolate was diagnosed as belonging to clade A following visual inspection of amplification curves. Low fluorescence intensity and late CT values (>40.0) was observed for this sample when tested using the B-Apn2 assay. bIsolate PA-50183 produced a positive diagnosis from both A-Apn2 and B-Apn2 assays, consistent with RFLP fingerprint data [8] previously generated for this isolate. *No diagnosis could be made using either assay. Analysis with the NanoDrop spectrophotometer showed an overabundance of compounds at A230.

Table S2 Samples of non-target fungal species used as negative controls for Colletotrichum cereale real-time PCR assays. CT = cycle threshold.

Table S3 Summary of biological replicates of cultured samples of Colletotrichum cereale tested to determine clade membership (A or B) using real-time PCR assays. CT = cycle threshold.

Table S4 Fresh samples of plant tissue tested to determine presence or absence of Colletotrichum cereale and clade membership (A or B) using real-time PCR assays. CT = cycle threshold.

Table S5 Herbarium specimens of Colletotrichum cereale tested to determine clade membership (A or B) using real-time PCR assays. CT = cycle threshold. *Isolate was diagnosed as belonging to clade A following visual inspection of amplification curves. Low fluorescence intensity and late CT values (>40.0) was observed for this sample when tested using the B-Apn2 assay. bSequence analysis of the amplicon generated confirmed the presence of both genotypes in these samples (data not shown). cVisualization of the real-time PCR product through gel electrophoresis and the amplification product of conventional PCR reactions performed using the primers alone on the fungarium specimens yielded no detectable amplicons.

Acknowledgments

We gratefully acknowledge the U.S. National Fungus Collections for use of fungarium specimens; Shamal Budhdev for technical support; Donald Kobayashi for use of laboratory equipment; Dan Ward for help with the logistic regression analysis, and Tom Hsiang, Noel Jackson, John Kamiinski, Maria Tomasino-Peterson, Lane Tredway, Wakar Uddin, Frank Wong, Nrupali Patel and Guohong Cai for contributing fungal isolates.
