Glomerular Hyperfiltration Is Associated With Blood Pressure Abnormalities in Normotensive Normoalbuminuric IDDM Patients

MIRELA J. AZEVEDO, MD
MIRIAM PECIS, MD
JORGE L. GROSS, MD

OBJECTIVE — To analyze the blood pressure patterns in normoalbuminuric IDDM patients with glomerular hyperfiltration.

RESEARCH DESIGN AND METHODS — A controlled cross-sectional study of 38 normotensive normoalbuminuric (urinary albumin excretion rate <20 µg/min) IDDM patients (18 hyperfiltering [glomerular filtration rate >134 ml · min⁻¹ · 1.73 m⁻²] and 20 normofiltering) and 20 normal individuals matched for age, sex, and BMI was performed. The 24-h ambulatory blood pressure was monitored using an auscultatory technique (Pressurometer IV, Del Mar Avionics), the glomerular filtration rate was measured by ⁵¹Cr-labeled EDTA method, extracellular volume by the distribution volume of ⁵¹Cr-labeled EDTA, and the 24-h urinary albumin excretion rate by radioimmunoassay.

RESULTS — Mean nocturnal diastolic blood pressure was higher in hyperfiltering IDDM patients (70.4 ± 7.8 mmHg), when compared with the control group (65.1 ± 5.3 mmHg, P = 0.04). Diastolic blood pressure night:day ratio was higher in hyperfiltering IDDM patients (92.0 ± 8.6%), when compared with normofiltering IDDM patients (85.9 ± 4.8%) and control subjects (87.0 ± 6.8%, P = 0.02). In IDDM patients, the glomerular filtration rate significantly correlated with the diastolic blood pressure night:day ratio (r = 0.5, P = 0.002), extracellular volume (r = 0.4, P = 0.002), and HbA₁c (r = 0.3, P = 0.03). In stepwise multiple regression analysis, factors associated with glomerular filtration rate were diastolic blood pressure night:day ratio, extracellular volume, and HbA₁c (adjusted r² = 0.27, P = 0.003).

CONCLUSIONS — Glomerular hyperfiltration is associated with higher nocturnal diastolic blood pressure and with a blunted nocturnal decrease in diastolic blood pressure levels in normotensive and normoalbuminuric IDDM patients.

An increased glomerular filtration rate (GFR) has been considered a risk factor for the development of diabetic nephropathy in IDDM patients (1). However, the role of glomerular hyperfiltration remains controversial. In a 10-year prospective study, baseline albumin excretion rate and blood pressure (BP) were the main risk factors for renal outcome. Baseline GFR was an independent determinant of final blood pressure (2).

Increased levels of arterial BP were detected in normoalbuminuric IDDM patients who progress to microalbuminuria (3). Alterations in ambulatory BP (ABP) parameters were observed in normoalbuminuric IDDM patients (4-6) and have been associated with diabetes duration (6) and with higher urinary albumin excretion rate (UAER) levels (4), although within the normal range. Abnormalities of circadian BP variation were also described in microalbuminuric IDDM patients (7-9). However, GFR was not taken into account in these studies.

It can be hypothesized that if there were an association of glomerular hyperfiltration and abnormalities of BP homeostasis, it would be possible to identify IDDM patients with a higher risk for the development of diabetic nephropathy. Therefore, the aim of this study was to analyze BP patterns in normoalbuminuric normotensive IDDM patients with glomerular hyperfiltration.

RESEARCH DESIGN AND METHODS

Subjects and methods This study followed a controlled cross-sectional design. Thirty-eight IDDM patients belonging to a cohort, which is being followed since 1986–1989 at the diabetic outpatient clinic of the Hospital de Clinicas de Porto Alegre (a tertiary care center), were studied. The GFR and UAER of these patients are being measured at ~1-year intervals (10). Informed consent was obtained from each patient, and the protocol was approved by the ethics committee. The definition of IDDM was based on World Health Organization criteria (11), i.e., onset of diabetes age <40 years, a previous episode of ketoacidosis or documented ketonuria, and obligatory use of insulin for life maintenance. The inclusion criteria were as follows: diabetes duration for >1 year; >18 years of age; 24-h UAER <20 µg/min on at least two different occasions; office ambulatory BP <140/90 mmHg; absence of coronary heart disease (normal maximal exercise electrocardiogram) or other cardiac disease; absence of renal disease (normal urinary sediment and negative culture); and absence of autonomic neuropathy (more than one abnormal result out of five cardiovascular
Hypermfiltration and blood pressure

Table 1—Clinical characteristics of IDDM patients and control group

|                      | Hyperfiltering | Normofiltering | Control |
|----------------------|----------------|----------------|---------|
| n                    | 18             | 20             | 20      |
| Age (years)          | 32.1 ± 6.4 (22–40) | 34.8 ± 7.8 (22–51) | 32.7 ± 6.0 (22–47) |
| Sex (FM)             | 10/8           | 9/11           | 10/10   |
| Ethnicity (black/white) | 4/14         | 1/19           | 2/18    |
| BMI (kg/m²)          | 24.3 ± 3.8 (18.2–30.0) | 22.0 ± 2.1 (18.4–24.8) | 23.6 ± 2.3 (20.0–27.5) |
| Smokers              | 6              | 3              | 4       |

| Background retinopathy | 4            | 2              |        |
| Peripheral neuropathy | 3             | 2              |        |

Data are n or means ± SD (range). All P values are nonsignificant.

autonomic reflex tests [12]). None of the patients were obese (BMI < 30 kg/m²).
Patients were conventionally treated with one or two daily subcutaneous insulin
injections, except for one patient who took four injections per day. Office auscultatory
BP was measured twice in a sitting position after a 10-min rest, with a standard 12.5-
cm cuff mercury sphygmomanometer (phases I–V), and the mean BP value was
used. These patients were classified as hyperfiltering (n = 18) and as normofiltering
(n = 20) according to the upper limit of normal GFR range previously established
in normal volunteers at our unit (mean + 2 SD = 134.0 ml · min⁻¹ · 1.73 m⁻² [13]).
The condition of hyperfiltration and normofiltration was confirmed at least three
times before the experiment, and 20 healthy individuals matched to the patients
for age, sex distribution, BMI, ethnicity, smoking habit, and use of oral contracep-
tives formed the control group.

The same researcher installed the 24-h ABP monitors in the morning. Patients and
control subjects were asked to continue their daily activities and to complete a 24-
h report on values of home glucose moni-
toring (before breakfast, lunch, dinner, at 10:00 P.M., and if hypoglycemia was sus-
pected), number of cigarettes smoked, and other exceptional activities (for instance, extra physical activity or arguing).

The 24-h ABP was measured with a lightweight battery-operated ambulatory
BP monitoring device (Pressurometer IV, Del Mar Avionics, Irvine, CA) using an
auscultatory technique. Before sampling, the pressurometer programmer, a micro-
computer used with the Pressurometer IV
program, was used to test and program the monitor. The programmer is also used
together with the test kit to calibrate the pressurometer against a mercury manome-
ter to ensure proper transducer placement and sensitivity. After sampling, the pro-
grammer can be interfaced with a printer to generate a comprehensive tabular report
showing sampling times and unedited systo-
dolic, diastolic, and heart rate readings. The monitor was programmed to take
measurements every 10 min from 7:00 A.M. to 11:00 P.M. and every 15 min from
11:00 P.M. to 7:00 A.M.. The mean diurnal and nocturnal BP and heart rate were cal-
culated based on each patient's self-
recorded time for going to bed and rising in the morning.

The GFR was measured using the ⁵¹Cr-
labeled EDTA single injection technique (coefficient of variation [CV] = 11.2%) and
calculated as a monoeponential function of the plasma disappearance curve accord-
ing to Chantler and Barrat (14). Extracellu-
lar volume (ECV) was estimated as the
distribution volume of ⁵¹Cr-labeled EDTA
(15). UAER was determined by radioim-
unoassay (DPC, Los Angeles, CA; inter-
and intra-assay CV = 2.3 and 2.8%, respec-
tively) in 24-h sterile specimens. Glucose
was measured by the glucose-oxidase
method, HbA₁ by a microchromatographic system (Labtest; normal range: 5.3–8.0%), and fructosamine by a colorimetric method
(NBT reduction, Labtest; normal range:
1.87–2.87 mmol/l). creatinine by Jaffe's
reaction, urinary uria by a kinetic reac-
tion, urinary sodium by flame photometry,
and cholesterol, HDL, and triglycerides by
a colorimetric method.

Statistical analysis
The three groups were compared by analy-
ysis of variance (ANOVA) followed by the
Student's t test or Mann-Whitney's rank-
sum test was used to compare normofilter-
ing and hyperfiltering IDDM patients.
Differences between groups for discrete
variables were evaluated by the Fisher's
effect test and χ² test. Pearson's correlation
test was used for the correlation between
GFR and systolic and diastolic BP night-day
(N:D) ratios. To examine a nonlinear rela-
tion between the GFR and diastolic BP N:D
ratio, a statistical method to determine the
breakpoint of two lines (a changepoint
model) was used (16). Stepwise multiple
linear regression analysis were carried out to
determine the effects of different variables
on GFR variation. Data were expressed as
means ± SD, except for the UAER analysis,
for which median and range were used. P <
0.05 was considered significant.

RESULTS — The clinical characteristics of
IDDM patients and control subjects are
shown in Table 1. No difference was
observed when comparing age, sex, eth-
icity, BMI, smoking habits, number of
valid 24-h ABP readings, family history of
hypertension, and the number of tests per-
formed on leisure days (day-off) or working
days (day-in) among the three groups (P >
0.05). Duration of diabetes, insulin dose,
and presence of retinopathy and peripheral
neuropathy were similar in hyper- and nor-
mofiltering patients (P > 0.05).

When clinical and laboratory features
were compared between hyper- and nor-
mofiltering patients (Table 2), the only dif-
ferences observed were lower levels of triglycerides and serum creatinine and higher ECV levels in hyperfiltering patients. By definition, GFR was different between the two groups.

ABP and heart rate values are described in Table 3. The nocturnal diastolic BP was significantly higher in hyperfiltering patients when compared with the control group (ANOVA, \( P = 0.04 \); SNK < 0.05). Differences in the diurnal variation of ABP were addressed by calculating the N:D ratio. The diastolic BP N:D ratio was higher in hyperfiltering patients (81.5 ± 10.5%) and the control group (83.6 ± 6.8%), but it did not reach the conventional statistical significance level (ANOVA, \( P = 0.055 \)). The proportion of nondippers, defined in this study as the subjects in whom the reduction of diastolic BP was <10% from day to night, was higher in hyperfiltering patients (10/18) when compared with normofiltering patients (3/20) and the control group (6/20) (\( \chi^2, P = 0.02 \)), without any difference between normofiltering patients and the control group.

Table 2—Laboratory features of IDDM patients

|                  | Hyperfiltering | Normofiltering | \( P \)  |
|------------------|----------------|----------------|--------|
| \( n \)          | 18             | 20             |        |
| GFR (ml \( \cdot \) min\(^{-1} \cdot 1.73 \) m\(^{-2} \)) | 158.2 ± 13.9 (138.5-180.4) | 117.4 ± 13.1 (94.4-133.0) | <0.001 |
| ECVR (U/1.73 m\(^2 \)) | 23.0 ± 3.7 (17.4-30.9) | 19.6 ± 2.5 (14.6-23.1) | 0.002 |
| UAER (\( \mu \)g/min) | 4.4 (0.3-15.9) | 4.7 (0.1-16.5) | NS     |
| Hba\(_1\) (\%)   | 8.9 ± 2.2 (5.3-13.0) | 8.7 ± 1.8 (5.0-11.4) | NS     |
| Fasting plasma glucose (mmol/l) | 7.8 ± 4.9 (3.0-11.5) | 8.1 ± 4.8 (2.4-12.2) | NS     |
| Home glucose monitoring (mmol/l) | 7.9 ± 2.8 (4.4-13.9) | 7.7 ± 1.6 (4.2-9.72) | NS     |
| Fructosamine (mmol/l) | 3.75 ± 0.84 (2.23-5.91) | 3.48 ± 0.64 (2.39-4.77) | NS     |
| Cholesterol (mmol/l) | 4.4 ± 1.0 (3.0-6.6) | 4.4 ± 0.7 (3.3-6.1) | NS     |
| HDL (mmol/l)      | 1.4 ± 0.5 (0.7-2.5) | 1.3 ± 0.3 (0.8-2.0) | NS     |
| Triglycerides (mmol/l) | 0.7 ± 0.3 (0.2-1.3) | 1.1 ± 0.6 (0.5-2.3) | 0.04   |
| Creatinine (\( \mu \)mol/l) | 76.9 ± 15.9 (53.0-106.1) | 90.2 ± 10.6 (70.7-106.1) | 0.007  |
| 24-h urinary urea (g) | 9.1 ± 2.8 (5.4-14.3) | 7.6 ± 2.7 (3.6-14.1) | NS     |
| 24-h sodium excretion (mEq/h) | 21.6 ± 8.3 (11.9-33.8) | 20.0 ± 7.9 (8.0-30.0) | NS     |

Data are means ± SD (range) and for UAER are median (range). Home glucose monitoring represents the mean of four measurements per day.

Table 3—Ambulatory BP and heart rate patterns of IDDM patients and control group

|                  | Hyperfiltering | Normofiltering | Control |
|------------------|----------------|----------------|---------|
| \( n \)          | 18             | 20             | 20      |
| 24-h sBP (mmHg)  | 122.9 ± 10.1   | 114.9 ± 10.9   | 111.2 ± 9.5 |
| 24-h dBP (mmHg)  | 74.7 ± 6.7     | 75.3 ± 6.6     | 72.2 ± 5.6 |
| 24-h heart rate (beats/min) | 71.3 ± 6.7 | 68.6 ± 5.6 | 68.9 ± 5.2 |
| Diurnal sBP (mmHg) | 116.5 ± 11.9  | 119.9 ± 10.9  | 116.4 ± 10.6  |
| Diurnal dBP (mmHg) | 76.9 ± 7.1    | 78.4 ± 6.6    | 75.0 ± 6.1   |
| Diurnal heart rate (beats/min) | 74.3 ± 6.2 | 71.2 ± 5.3 | 70.7 ± 4.6 |
| Nocturnal sBP (mmHg) | 102.2 ± 10.2  | 97.7 ± 14.3   | 97.1 ± 9.9   |
| Nocturnal dBP (mmHg) | 70.4 ± 7.8    | 67.1 ± 6.3    | 65.1 ± 5.3*  |
| Nocturnal heart rate (beats/min) | 67.4 ± 9.1    | 62.2 ± 6.9    | 65.0 ± 10    |

Data are means ± SD. *\( P = 0.02 \), hyperfiltering vs. control. sBP, systolic blood pressure; dBP, diastolic blood pressure.

CONCLUSIONS—In this study, IDDM patients with glomerular hyperfiltration presented higher levels of nocturnal diastolic BP GFR was associated with a blunted decrease in diastolic BP, with increased ECV and Hba\(_1\). The diastolic BP N:D ratio was the main factor contributing for GFR variation. There is probably a threshold in GFR values above which there is an association with BP abnormalities. The breakpoint analysis disclosed that only GFR values >140 ml \( \cdot \) min\(^{-1} \cdot 1.73 \) m\(^{-2} \) presented a significant correlation with the diastolic BP N:D ratio. This GFR value is closer to the upper limit of GFR previously established in our unit of 134 ml \( \cdot \) min\(^{-1} \cdot 1.73 \) m\(^{-2} \).
Hyperfiltration and blood pressure

It is well known that GFR is influenced by the degree of metabolic control in IDDM (17) and NIDDM patients (18). In the present study, HbA1 variation accounted only for ~3% of the GFR variation. The relationship between GFR and ECV has already been reported by us (19) and others (20). Theoretically, the observed expansion of ECV could explain the abnormalities of the BP pattern in hyperfiltering IDDM patients. However, the blood volume was not different in a similar group of normofiltering and hyperfiltering IDDM patients (19). It could be speculated that during the night, in a recumbent position, there could be a redistribution of ECV leading to a transient increase in blood volume.

Higher levels of nocturnal BP in normotensive normoalbuminuric IDDM patients were also reported by other authors (5,6). In the study by Gilbert et al. (5), there is no mention as to whether ABP monitoring was performed on working or nonworking days. Another study (6) evaluated only male patients, and the authors did not mention smoking habits, the number of tests performed on working days, and the criteria used to define the night period. The authors compared patients with a diabetes duration of 12 years with patients with a diabetes duration of 2.4 years.

Diabetes duration has been reported to influence ABP patterns in normoalbuminuric IDDM patients (6,21). In those studies, the night heart rate was higher in patients with a longer duration of diabetes, possibly indicating the presence of vagal neuropathy. Neither of these studies had performed proper autonomic function tests. It has already been shown that autonomic dysfunction is associated with blunted decrease of nocturnal diastolic BP in normoalbuminuric IDDM patients (22). In our study, the patients did not present abnormalities in autonomic cardiovascular tests or a higher nocturnal heart rate. However, we could not exclude an early autonomic dysfunction if more sensitive methods had been applied. The effect of the longer duration of diabetes could, in fact, represent the presence of autonomic neuropathy.

Other authors have not found any significant difference in the BP N:D ratio between normoalbuminuric IDDM patients and healthy control subjects (23,24). In the study by Hansen et al. (23), ABP monitoring was performed more often on nonworking days (71% in IDDM patients and 75% in control subjects) than in the present study (24% in IDDM patients and 29% in the control group; P < 0.01 for both comparisons). The duration of diabetes was also longer (18 years) than in our subjects (7.5 years). In another study (24), the number of patients and healthy individuals was small (12 in each group), fixed night periods were used to calculate the nocturnal BP mean (11:00 P.M. to 7:00 A.M.), and
all the patients were admitted to hospital for the night measurements. The authors did not mention whether the normal individuals were also admitted to hospital.

The GFR was not measured in any of the studies mentioned above.

The association between GFR and an altered circadian BP rhythm could identify a subset of IDDM patients more susceptible to future development of diabetic nephropathy. Prospective studies of this particular group of patients should be conducted. In conclusion, in normotensive and normoalbuminuric IDDM patients, glomerular hyperfiltration is associated with a higher nocturnal diastolic BP and with a blunted nocturnal decrease in diastolic BP levels.
