We present the implementation of a new scheme to detect the quantum state of a persistent-current qubit. It relies on the dependency of the measuring SQUID plasma frequency on the qubit state, which we detect by resonant activation. With a measurement pulse of only 5ns, we observed Rabi oscillations with high visibility (65%).

PACS numbers:

Superconducting circuits containing Josephson junctions are promising candidates to be the building blocks (qubits) for future quantum computers [1]. Coherent dynamics has been observed with several different qubit designs. Complex sequences of rotations on the Bloch sphere could be performed in NMR-like experiments: Rabi, Ramsey, spin-echo, composite pulse sequences were demonstrated [2,3,4,5]. In these experiments, the detection of the qubit energy state is done after the coherent operations have been accomplished by reading out a macroscopic detector with an output that is correlated to the qubit energy eigenstate. By averaging the signal delivered, one infers the qubit eigenstate occupation probability.

A hysteretic DC SQUID has been successfully employed to measure the state of a flux-qubit [6] (a similar scheme was used in [8] in the case of a split Cooper pair box). In this experiment, a fast dc current pulse (DCP) sent through the SQUID induced switching to the finite-voltage state conditional on the qubit state. In this Rapid Communication, we propose and demonstrate a new read-out method, faster than the previous one, which does not require a large bandwidth line to inject current through the SQUID and thus will allow a stronger filtering of the bias lines. The method is based on the dependence of the SQUID plasma frequency on the qubit’s state measured by a resonant activation microwave pulse (RAP). We compare Rabi oscillations obtained by the two schemes in exactly the same conditions, and show that the RAP method significantly increases the contrast.

The persistent-current qubit consists of a micron-size superconducting loop intersected with three Josephson junctions [6]. It is threaded by a magnetic flux $\Phi_x$ generated by an external coil. When the total phase across the three junctions $\gamma_0$ is close to $\pi$ (meaning that $\Phi_x$ is close to $\Phi_0/2$), the loop has two low-energy eigenstates (ground state 0 and excited state 1) well separated from the higher-energy ones, and can thus be used as a qubit. They are linear combinations of two states $|\uparrow\rangle$ and $|\downarrow\rangle$ which carry an average persistent-current of $+I_p$ and $-I_p$ and are coupled by tunnelling. The effective hamiltonian reads $H = -\hbar (\sigma_x/2 - \Delta \sigma_x/2)$ in the $\{|\uparrow\rangle, |\downarrow\rangle\}$ basis, where $\hbar \Delta /2$ is the tunnelling matrix element between the two basis states, and $\epsilon = 2I_p (\Phi_x - \Phi_0/2)/\hbar$. This leads to an energy separation between the two states $E_1 - E_0 \equiv h f_q = \hbar \sqrt{\Delta^2 + \epsilon^2}$. The average current in state $i$ ($i = 0, 1$) $I_i = -e \partial H / \partial \Phi_x |_{\epsilon}$ can be computed from the previous equations. It is shown in figure [7] for the parameters of our sample. The qubit is inductively coupled to a hysteretic DC-SQUID whose critical current depends on $I_x$ by an amount $\alpha M I_x$, where $M$ is the mutual inductance between the qubit and the SQUID, and $\alpha = \partial I_C / \partial \Phi_x$ is the slope of the SQUID modulation curve. The requirement imposed upon any detection scheme is to detect the small (about 2%) variation in the SQUID critical current associated with a transition between the qubit states in a time shorter than the qubit’s energy relaxation time $T_1$. A first method was demonstrated in [3,4,6]. It consists of applying a short DCP to the SQUID at a value $I_0$ during a time $\Delta t$, so that the SQUID will switch out of its zero-voltage state ($\Phi_0$) with a probability $P_{sw} (I_0)$. For well-chosen parameters, the detection efficiency $D = \max_{I_0} |P_{sw}^1 - P_{sw}^0|$, where $P_{sw}^0$, ($P_{sw}^1$) is the switching probability if the qubit is in the ground (excited) state, can approach 1. The switching probability then directly measures the qubit’s energy level population.

The Al/AlO$_x$/Al tunnel junctions as well as the SQUID and qubit’s aluminium loops were obtained by e-beam lithography and shadow-evaporation on an oxidized silicon substrate. The SQUID was shunted by an on-chip aluminium capacitor and connected to the current injection line through a 400 $\Omega$ on-chip gold resistor (see figure [8]). Both current and voltage line were filtered by copper-powder filters [9]. The voltage across the SQUID was amplified at room-temperature and sampled by an acquisition card. By repeating the measurements typically 10000 times at a rate of 25 k$Hz$ we derive

the switching probability. Pulsed microwave irradiation was applied to the qubit through a coaxial cable attenuated by 20 dB at $T = 1.5 \, K$. The sample was enclosed in a copper box thermally anchored to the mixing chamber of our dilution refrigerator (base temperature 25 mK) to shield it from RF noise.

The parameters of our qubit were determined by fitting spectroscopic measurements with the above formulae. For $\Delta = 5.855 \, GHz$, $I_p = 272 \, nA$, the agreement is excellent (see figure 2). We also determined the coupling constant between the SQUID and the qubit by fitting the qubit “step” appearing in the SQUID’s modulation curve (see insert of figure 1) and found $M = 20 \, pH$. We first performed Rabi oscillation experiments with the DCP detection method (figure 1c). We chose a bias point $\Phi_x$, tuned the microwave frequency to the qubit resonance and measured the switching probability as a function of the microwave pulse duration $t_{mw}$. The observed oscillatory behavior (figure 1b) is a proof of the coherent dynamics of the qubit. A more detailed analysis of its damping time and period will be presented elsewhere; here we focus on the amplitude of these oscillations.

In the data shown here, the contrast is 32%, but we observed a strong dependence on the exact bias point, ranging between 5% and 40%. This visibility was lower than in our previous experiment [3]. We checked that the amplitude $I_b$ of the current pulse was optimal by measuring the switching probability as a function of $I_b$ both without microwave ($P_{sw}^0(I_b)$) and after a $\pi$ pulse ($P_{sw}^\pi(I_b)$). Typical data are shown in figure 2a. The solid black curve $P_{sw}^0(I_b)$ is a fit to $P_{sw}^0(I_b)$ assuming that switching occurs by thermal activation across the potential barrier [3]. The dotted line $P_{sw}^\pi(I_b)$ was calculated with the same parameters assuming that the qubit is always in 1. The curve $P_{sw}^\pi(I_b)$ is then well approximated by a weighted sum of the curves $P_{sw}^\pi(I_b)$ and $P_{sw}^0(I_b)$ with coefficients $p_g = 0.68$ and $p_o = 0.32$ (grey solid line). From this we conclude that the detection efficiency $D$ of our detector, as designed, should be of at least 85%, but that the excited state of our qubit is only populated up to 32% when switching to the running state occurs at the end of the DCP. Thus, it seems that the qubit partially relaxes towards its ground state during the measurement process. As we will show below, this problem does not occur with the alternative measurement scheme described hereafter.

The SQUID, connected to the capacitor $C_{sh}$ by aluminum wires of inductance $L$, behaves as an oscillator with a characteristic frequency called the plasma frequency $2\pi f_p = [(L + L_J)C_{sh}]^{-1/2}$. This frequency depends on the bias current $I_b$ and on the critical current $I_C$ via the Josephson inductance $L_J = \Phi_0/(2\pi I_C \sqrt{1 - I_b^2/I_C^2})$. Thus, the plasma frequency takes different values $f_p^{(0)}$ or $f_p^{(1)}$ depending on the qubit’s state. This effect has already been observed in [10] by measuring the transmission of a weak probe at a frequency close to $f_p$ while keeping the SQUID in the

![FIG. 1: (a) AFM picture of the SQUID and qubit loop (the scale bar indicates 1 µm). Two layers of Aluminium were evaporated under $± 20 \, ^\circ$ with an oxidation step in between. The Josephson junctions are formed at the overlap areas between the two images. The SQUID is shunted by a capacitor $C_{sh} = 12 \, pF$ connected by Aluminium leads of inductance $L = 170 \, pH$ (solid black line). The current is injected through a resistor (grey line) of 400 $\Omega$. (b) DCP measurement method: the microwave pulse induces the designed Bloch sphere rotations. It is followed by a current pulse of duration $20 \, ns$, whose amplitude $I_b$ is optimized for the best detection efficiency. A 400 $ns$ lower-current plateau follows the DCP and keeps the SQUID in the running-state to facilitate the voltage pulse detection. (c) Larmor frequency of the qubit and (insert) persistent-current versus external flux. The squares and (insert) the circles are experimental data. The solid lines are numerical adjustments giving the tunnelling matrix element $\Delta$, the persistent-current $I_p$ and the mutual inductance $M$.](image1)

![FIG. 2: (a) Rabi oscillations at a Larmor frequency $f_q = 7.15 \, GHz$ (b) Switching probability as a function of current pulse amplitude $I$ without (closed circles, curve $P_{sw}^0(I)$) and with (open circles, curve $P_{sw}^\pi(I)$) a $\pi$ pulse applied. The solid black line $P_{sw}^\pi(I_b)$ is a numerical adjustment to $P_{sw}^0(I_b)$ assuming escape in the thermal regime. The dotted line (curve $P_{sw}^\pi(I_b)$) is calculated with the same parameters for a critical current 100$nA$ smaller, which would be the case if state 1 was occupied with probability unity. The grey solid line is the sum $0.32P_{sw}^0(I_b) + 0.68P_{sw}^\pi(I_b)$.](image2)
zero-voltage state. With a probe of larger power, it has recently been demonstrated that a Josephson junction could switch between two distinct oscillation states while staying in the zero-voltage regime, due to its non-linearity [11]. Such a bifurcation amplifier could be used to detect the state of a charge qubit [12]. Here we apply a microwave pulse at a frequency close to $f_p^0$. We adjust the power so that the SQUID switches to the finite voltage state by resonant activation [14] if the qubit is in state $|0\rangle$, whereas it stays in the zero-voltage state if it is in state $|1\rangle$. If the two resonant activation peaks corresponding to the frequencies $f_p^0$ and $f_p^1$ are distinct enough, the switching probability of the SQUID measures the probability that the qubit is in the state $|0\rangle$. Similarly, in [4], the quantum state of a current-biased Josephson junction (phase-qubit) has been detected by applying a microwave pulse that induces switching determined by the qubit state. In our experiment, the detector is distinct from the qubit. Although switching to the finite-voltage state is a dissipative process potentially harmful for quantum computation, the specific interest of this scheme is that it allows to heavily filter the bias-current line since no fast DC or RF pulse is needed there.

A typical resonant activation peak is shown in the insert of figure 3. Its width depends on the frequency, ranging between 20 and 50 MHz. This corresponds to a quality factor between 50 and 150. The peak has an asymmetric shape, with a very sharp slope on its low-frequency side and a smooth high-frequency tail, due to the SQUID non-linearity. We could qualitatively recover these features by simple numerical simulations using the RCSJ model [13]. The resonant activation peak can be unambiguously distinguished from environmental resonances by its dependence on the magnetic flux threading the SQUID loop $\Phi_{sq}$. Figure 4 shows the measured peak frequency for different fluxes around $\Phi_{sq} = 1.5\Phi_0$, together with the measured switching current (dashed line). The solid line is a numerical fit to the data using the above formulae. From this fit we deduce the following values $C_{sh} = 12 \pm 2pF$ and $L = 170 \pm 20pH$, close to the design. We are thus confident that the observed resonance is due to the plasma frequency.

We then measure the effect of the qubit on the reso-
nant activation peak. The principle of the experiment is sketched in figure 4a. A first microwave pulse at the Larmor frequency induces a Rabi rotation by an angle $\theta_1$. A second microwave pulse of duration $\tau_2 = 10\,\text{ns}$ is applied immediately after, at a frequency $f_2^\prime$ close to the plasma frequency, with a power high enough to observe resonant activation. In this experiment, we apply a constant bias current $I_b$ through the SQUID ($I_b = 2.85\mu\text{A}$, $I_b/I_C = 0.85$) and maintain it at this value 500 ns after the microwave pulse to keep the SQUID in the running state for a while after switching occurs. This allows sufficient voltage to build up across the SQUID and makes detection easier, similarly to the plateau used at the end of the DCP method in exactly the same conditions (grey curve). The contrast is significantly improved, while the dephasing time is evidently the same. This enhancement is partly explained by the rapid 5 ns RAP (for the data shown in figure 4A) compared to the 30 ns DCP. But we can not exclude that the DCP intrinsically increases the relaxation rate during its risetime. Such a process would be in agreement with the fact that for these bias conditions, $T_1 \simeq 100\,\text{ns}$, three times longer than the DCP duration.

In conclusion, we demonstrated a new method for detecting the state of a persistent-current qubit. We exploited the dependence of the SQUID’s plasma frequency on the qubit’s state which we measured by applying a microwave pulse that induces resonant activation. It provided large detection efficiency even for short microwave pulses (5 ns). The contrast of the Rabi oscillations was mainly limited by the resonant activation peaks separation. By improving the quality factor of the plasma oscillator and using composite pulses, we might thus reach the single-shot regime while keeping the bias current line heavily filtered and having a large dephasing time.
