complication in mandibular fracture fixation using the absorbable fixator method. Normally, where mass growth is initiated in an acute postoperative period, primary infection is most likely considerable. However, in the case described above, where the mass showed late growth, circumstantial evaluation of the mass itself is important. Accurate knowledge of types of complication will eventually be helpful in proper management of operation site mass genesis.

The genus Fusarium is widespread in soil, plants, and the air, and broad manifestations of human disease
can be caused by infection with it, which can be superficial, locally invasive, or disseminated infections, including mycotoxicosis [1]. One of the most frequent aspects of infection by *Fusarium* species is the development of skin lesions; such lesions are typically the only source for diagnosis [2]. Thus, diagnosis and treatment of human *Fusarium* infection is usually delayed, causing poor results.

We report on a case of cutaneous fusariosis caused by continuous soil and plant contamination of an open wound that formed after a snake bite on the hand. The infection was ultimately treated and there was no recurrence after three months.

The patient was an 81-year-old, otherwise healthy woman. She was a farmer and had a history of abusing oral corticosteroids due to arthritis from approximately five years until one year ago (2006 to 2011). She was transferred to our hospital with a painful progressive skin ulceration around her right third knuckle and proximal phalanx after a snake bite two weeks earlier (Fig. 1). After the snake bite, she continued working on the farm without wound protection and the bite wound worsened.

First, because she was healthy, the lesion was evaluated for bacterial infection and methicillin-resistant *Staphylococcus aureus* was cultured from a swab specimen. Intravenous vancomycin was continued for two weeks and the patient underwent serial surgical debridement, and, two weeks later, a full-thickness skin graft surgery was performed. However, one week after surgery, progressive eschar formation was observed from the distal tip of the graft to the distal aspect. At three weeks after surgery, a skin defect and eschar formed from the distal half of the grafted skin to the middle third of the proximal phalanx. We expected possibility of other kind of infection because wound healing was delayed and she has a history of working on the farm without wound protection and the bite wound worsened.

First, because she was healthy, the lesion was evaluated for bacterial infection and methicillin-resistant *Staphylococcus aureus* was cultured from a swab specimen. Intravenous vancomycin was continued for two weeks and the patient underwent serial surgical debridement, and, two weeks later, a full-thickness skin graft surgery was performed. However, one week after surgery, progressive eschar formation was observed from the distal tip of the graft to the distal aspect. At three weeks after surgery, a skin defect and eschar formed from the distal half of the grafted skin to the middle third of the proximal phalanx. We expected possibility of other kind of infection because wound healing was delayed and she has a history of working on the farm without wound protection. She was readmitted to the hospital, and a tissue biopsy was taken. Microscopic examination of the surgical specimen revealed fungal hyphae and necrotic tissue (Fig. 2). However, there was no evidence of immunocompromised status, such as neutropenia basis her laboratory finding and there was not any other systemic symptom. A diagnosis of cutaneous fusariosis was made, and the patient underwent aggressive surgical debridement.

Intravenous amphotericin B (Fungizone 50 mg; BMS Pharmaceutical Korea Ltd., Seoul, Korea) 1 mg/kg daily, was started and continued for one week and switched to oral voriconazole (Vfend 200 mg; Pfizer Inc., Seoul, Korea) 200 mg twice daily for four weeks. After ensuring that there were no fungal hyphae or fungi growth in tissue culture, a second operation (full-thickness skin graft) was performed. Six months after the operation, there was no evidence of recurrence (Fig. 3).

The genus *Fusarium* is widely distributed in plants and soil in temperate and tropical climates. Microscopically, the hyphae of *Fusarium* have multiple filaments, which are hyaline, septate, 3–8 µm in diameter, and typically branch at acute or right angles. The most frequent human *Fusarium* isolates are *Fusarium solani*, *Fusarium oxysporum*, and *Fusarium proliferatum*, however, species differentiation may be difficult except in specialized laboratories [3]. *Fusarium* species possesses several virulence factors, including the production of tricothecene and other mycotoxins. These mycotoxins can suppress humoral and cellular immunity, and cause break down of tissue [4]. Such skin breakdown may precede infection by up to one year [2].

The majority of immunocompetent patients (77%) have a history of recent skin breakdown at the lesion of cutaneous fusariosis, either as a result of trauma (54%) or preexisting onychomycosis (23%) [2]. Skin lesions may vary, including granulomas, ulcers, nodules, mycetomas, necrosis, panniculitis, and intertrigo [5].

For the diagnosis of cutaneous fusariosis, a meticulous physical examination is required for identification of suspicious skin lesions with tissue breakdown and all suspicious lesions should be
In our case, because methicillin-resistant *Staphylococcus aureus* infection was demonstrated by culture, a fungal infection was not considered initially and diagnosis was delayed. In addition, the patient had a history of long-term corticosteroid abuse, which had likely weakened her immune resistance to infection and had caused thinning of her skin. Her skin was broken by a snake bite, and she continued to work on a farm even after the bite without protecting the wound. These events allowed continuous penetration of *Fusarium* and might easily have enabled colonization.

In a patient who has chronic wounds with sustained farming, fungal infection should be suspected. Also, because skin breakdown due to infection may precede illness by up to one year, it is necessary to obtain a detailed history of the patient's behavior. In addition, a tissue biopsy should be recommended because it provides the only diagnostic clue.
