(Dated: March 30, 2008)
well as oscillation results are statistically consistent with the first phase and do not show spectral distortion. The time-dependent flux measurement of the combined first and second phases coincides with the full period of solar cycle 23 and shows no correlation with solar activity. The measured $^8\text{B}$ total flux is $(2.38 \pm 0.05\text{(stat.)} \pm 0.16\text{(sys.)}) \times 10^6 \text{cm}^{-2}\text{sec}^{-1}$ and the day-night difference is found to be $(-6.3 \pm 4.2\text{(stat.)} \pm 3.7\text{(sys.)})\%$. There is no evidence of systematic tendencies between the first and second phases.

I. INTRODUCTION

The first phase of the Super-Kamiokande experiment, SK-I [1-2], yielded high precision measurements of the solar neutrino flux. In spite of the loss of numerous photomultiplier tubes [PMT] sustained in an accident, SK continued to collect data with reduced photo-cathode coverage and a higher energy threshold. Data collection and analysis methods had to be revised due to the loss of detector sensitivity. Super-Kamiokande’s second phase [SK-II] ran from December 2002 to October 2005.

Throughout this paper, the methods and results of SK-II are compared with SK-I and, when differing, are detailed for SK-II.

II. SK-II PERFORMANCE

A. Detector Simulation

It was determined that the November 12th, 2001 accident sustained by the SK detector was caused by a propagating shock wave initiated by an imploding PMT located at the bottom of the inner detector. Therefore, blast shields were installed to protect the PMTs against such a chain reaction. These shields are 1.0 cm-thick transparent acrylic domes allowing light to pass to the PMTs’ photo-sensitive surface. This presents an additional medium through which Cherenkov light must travel. Reflection and refraction of light on the acrylic surface is accounted for in the SK-II GEANT 3 Monte Carlo detector simulation. The acrylic shields’ transparency at normal incidence is better than 98% above 400 nm in wavelength. It is about 86% at 300 nm.

For light propagation in water, both SK-I and SK-II adopt a 3-part model of light attenuation consisting of Rayleigh scattering, Mie scattering, and absorption. We consider two types of absorption: long wavelength ($\lambda > 350$ nm) and short wavelength ($\lambda \leq 350$ nm) absorption. In the long wavelength absorption region, we utilize an independent model derived using direct measurements from an integrating chamber absorption meter [ICAM] applied to pure water [3]. Scattering coefficients and absolute short wavelength absorption are tuned to reproduce energy distributions in LINAC calibration data (see section II.C for a description of the LINAC data). At short wavelengths, the SK-I model varies the absorption coefficient to describe the changing SK in-tank water transparency as measured by decay electrons from cosmic-ray muons. In SK-II, the best description has no short wavelength absorption but increased scattering. Figure 1 shows the attenuation model in both short and long wavelengths for SK-II.

In determining the expected solar neutrino flux spectrum for a range of oscillation parameters, SK-II follows the method of SK-I: the total $^8\text{B}$ and hep flux values of the BP2004 Standard Solar Model (SSM) [4] are used with the neutrino spectrum based on the $\beta$-delayed $\alpha$ spectrum of $^8\text{B}$ decay by Ortiz [5] to calculate the flux of a particular energy bin. The uncertainties of the neutrino spectrum are taken from Bahcall [6].

B. Event Reconstruction

1. Vertex

The determination of event vertex, direction, and energy with the reduced light collection capability of SK-II has prompted the development of new reconstruction methods. For vertex reconstruction, the efficiency of the SK-I standard vertex fit significantly drops at energies below the SK-I analysis threshold of 5.0 MeV. With 40% photocathode coverage, this corresponds to roughly 25 PMT signal hits. At 19% coverage in SK-II, 25 hits translates to 8 MeV.

The timing residual in an event is defined as the time difference between a PMT’s hit time $t_i$ and the emission

![FIG. 1: Wavelength dependence of the water parameter combined SK-II absorption-reflection coefficient.](image-url)
time \( t_0 \) (fitted to minimize all timing residuals) minus the time it would take Cherenkov light to reach that PMT given the event’s vertex \( \vec{v} \) in the tank:

\[
t_{\text{residual}} = (t_i - t_0) - |\vec{v} - \vec{h}_i|/c,
\]

(2.1)

where \( \vec{h}_i \) is the vector location of the hit PMT and \( c \) is the group velocity of light in water.

In SK-I, vertex reconstruction is accomplished by selecting a limited number of hit PMTs from an event (to reduce bias from PMT dark noise and scattered light hits) and calculating a goodness relation based on the timing residuals of the selected hits and a candidate vertex \( \vec{v} \). A systematic grid search of candidate vertices is performed until the goodness reaches a maximum value. After that, the vertex position is fine-tuned to further maximize the goodness. The SK-I reconstruction will not attempt a vertex fit for less than 10 hits.

In contrast, the SK-II reconstruction uses all hits from an event to form the timing residuals for determination of the vertex position. Bias from PMT dark noise is reduced by constructing a likelihood describing the shape of the timing residual distribution from LINAC calibration data. This likelihood is then maximized from a vertex search based not on a grid pattern but from a list of vertex candidates calculated from PMT hit combinations of 4 hits each. The four-hit combinations each define a unique vertex given their timing constraints. Any event with four hits or more is reconstructed.

SK-II also makes use of the SK-I goodness-grid search method in its online and initial offline analysis for filtering background events. The final reconstruction, or the standard fit based on the residual likelihood method, is the final determination of vertex position and can also be seen as a correction for any misreconstructed events which survived the filtering process. Figure 2 shows the various vertex resolutions for the SK-II vertex reconstruction. The uncertainty of the measured solar neutrino rate due to systematic shifts in vertex position is estimated to be 1.1%.

Both SK-I and SK-II utilize a fast fit online reconstruction method for pre-filtering low energy events. Details can be found elsewhere \[2\].

2. Direction

The direction reconstruction is identical to the SK-I method: a likelihood function is used to compare Cherenkov ring patterns between data and MC distributions. Opening angles between the particle direction and reconstructed vertex-to-hit PMT position are scanned using grid searches at varying levels of precision. The SK-II standard fitter is used to determine the vertex. The absolute angular resolution (defined as the maximum angular difference between 68% of the reconstructed and true event directions as determined by MC) of SK-II differs from SK-I by about 10% and is mostly limited by detector coverage but by multiple scattering of electrons in the tank. The difference between data and MC angular resolutions, however, is greater in SK-II due to the larger discrepancies in energy scales between data and MC. Therefore, we assign an angular resolution systematic error of 6.0%. Angular resolution is shown in Figure 3.

3. Energy

The reconstruction of event energy is identical to that of SK-I with modification specific to SK-II (photo-cathode coverage, blast shields, etc.). From the number of in-time hit PMTs (coincident within 50 ns) from an event \( (N_{\text{hit}}) \), various corrections are made. The resulting effective hit sum has a consistent value throughout the detector for a given event \( (N_{\text{eff}}) \). From \( N_{\text{eff}} \), we determine energy. Refer to \[2\] for specific information on the conversion from \( N_{\text{hit}} \) to \( N_{\text{eff}} \).
The \( N_{\text{eff}} \)-to-energy conversion function must be modified for SK-II due to smaller values of \( N_{\text{eff}} \) corresponding to equivalent energies with larger \( N_{\text{eff}} \) in SK-I. This is done by generating MC events at discrete input energies between 5 and 80 MeV, calculating their \( N_{\text{eff}} \) values, and then interpolating the energy function. As with SK-I, energy refers to total energy of the event (kinetic energy plus electron rest mass).

Since the corrections in \( N_{\text{eff}} \) depend on the water transparency, the reconstructed energy also varies slightly with changing water quality. See Figure 4 for \( N_{\text{eff}} \) as a function of time for a given water transparency.

An analytical function of the detector’s energy resolution can be determined with the same MC events used for the \( N_{\text{eff}} \)-to-energy conversion function. The energies of the MC events are calculated from the method described above and their fitted Gaussian mean energy and corresponding 1 sigma values are plotted for each discrete energy. A sigma function \( \sigma(E) \) is then fitted to use in a normal Gaussian probability density function

\[
P(E, E') = \frac{1}{\sqrt{2\pi} \sigma} \exp \left[ -\frac{(E' - E)^2}{2\sigma^2} \right],
\]

where \( E \) is the electron’s true recoil energy and \( E' \) is the reconstructed energy. The function \( \sigma(E) \) for SK-II is given by

\[
\sigma(E) = 0.0536 + 0.5200\sqrt{E} + 0.0458E,
\]

in units of MeV. The SK-I resolution is \( \sigma = 0.2468 + 0.1492\sqrt{E} + 0.0690E \). Both resolutions are shown in Figure 5. Equation 2.2 with Equation 2.3 can be used to apply the SK resolution when calculating theoretical spectra for comparison with SK data.

C. LINAC and \( ^{16}\text{N} \) Energy Calibration

As with SK-I, the primary instrument for energy calibration in SK-II is an electron linear accelerator [LINAC]. Detailed discussions on the LINAC calibration methods can be found elsewhere [7]. Electrons are injected into the SK tank at various positions (see Figure 6) at energies between 5.8 and 13.4 MeV. After reconstructing the energies of LINAC events, these data are compared with MC to determine the deviation in energy scales. Various MC parameters are then adjusted to minimize the differences (see section II.A).

The minimum uncertainty in the SK-II absolute energy scale using 13.4 and 8.8 MeV LINAC data is calculated to be 1.4%. This is in contrast to the SK-I estimated value of 0.64%. Figure 6 shows the relative difference of reconstructed energies of LINAC data and MC as well as their differences in energy resolution.

\( ^{16}\text{N} \) is also used as a calibration source in conjunction with the LINAC calibration [8]. \( ^{16}\text{N} \) is produced by lowering a deuterium-tritium neutron generator into the tank and initiating the fusion reaction \( ^2\text{H} + ^3\text{H} \rightarrow ^4\text{He} + n \). A fraction of these 14.2 MeV neutrons collide with \( ^{16}\text{O} \) in the water to produce \( ^{16}\text{N} \) which then decays with a half-life of 7.13 seconds. In most cases, the Q-value is shared between 6.1 MeV gamma rays and a \( \beta \)-decay electron.

\( ^{16}\text{N} \) decays allow directional studies on the energy scale not capable with the unidirectional LINAC beam. At a
FIG. 6: The LINAC system at SK. The dotted line represents the fiducial volume of the detector and the numbers 1-6 indicate where LINAC data were taken in SK-II.

The total $^{16}$N decay product energy of 10.4 MeV, observed energy at several tank positions is compared with MC-simulated energy and the difference is shown to agree with those obtained from LINAC data and MC. The $^{16}$N energy scale difference is averaged to be $\pm 1.2\%$ compared with LINAC’s $\pm 1.4\%$. In addition, the isotropic $^{16}$N data are divided into zenith angle bins to show the relative asymmetry of the energy scale. These show asymmetries within $\pm 0.5\%$ (Figure 7) and are similar with SK-I values.

Quantitative representations of trigger efficiencies are also obtained from $^{16}$N data. The lowest threshold where the SK-II trigger is 100% efficient is 6.5 MeV whereas the SK-I threshold is 4.5 MeV. Figure 8 shows the trigger efficiencies for SK-II. A systematic error is assigned to the trigger efficiency by comparing the value given by $^{16}$N data and MC-simulated trigger events (0.5% on the total flux measurement).

III. DATA ANALYSIS

A. Trigger Scheme

Like SK-I, SK-II has two levels of triggering for solar neutrino analysis: low energy [LE] and super-low energy [SLE] thresholds which require a minimum of about 14 and 10 hit PMTs respectively to register an event. At the beginning of data taking in December 2002, only the LE trigger threshold was applied. At and above 8.0 MeV is where the LE trigger is 100% efficient. Later, the threshold was lowered and SLE data was taken with 100% efficiency at 6.5 MeV. Ultimately, the LE+SLE analysis threshold was set to 7.0 MeV due to the large number of background events below this level. The LE analysis period lasted from December 24th, 2002 to July 14th, 2003 for an exposure of 159 live days. The LE+SLE period lasted from July 15th, 2003 until October 5th, 2005 for an exposure of 632 live days.

SLE triggered events are filtered online to reduce the amount of data written to limited storage space. Events reconstructed outside the fiducial volume are rejected. The data are reduced by a factor of approximately six. See Fig 2 for the vertex resolution as a function of energy of the online fitter.

B. Background Reduction

For SK-II, we implement a new two-part cut of events based on defined goodness functions of PMT timing and hit patterns.

Many background events remain due to mis-reconstruction after the usual two-meter fiducial volume cut, (which reduces background coming from the PMTs and blast shields.) Whereas a gamma-ray cut solely relies on vertex and directional reconstruction, the 2-dimensional timing-pattern cut removes those events whose reconstruction should not be trusted. An optimized hit PMT timing goodness is defined (Equation 3.1) by comparing two timing residual Gaussian distributions, one with a width of $\sigma = 5$ ns to encompass selected hits and the other with a $\omega = 60$ ns width characteristic of the PMT timing resolution for a single photo-electron:

$$g_t(\vec{v}) = \frac{\sum e^{-\frac{1}{2} \left( \frac{(\tau_i(\vec{v}) - t_0)^2}{\sigma^2} + (\tau_i(\vec{v}) - t_0)^2}{\omega^2} \right)}}{\sum e^{-\frac{1}{2} \left( \frac{(\tau_i(\vec{v}) - t_0)^2}{\omega^2} \right)}}.$$

The effective hit time is defined as $\tau_i(\vec{v}) = t_i - |\vec{v} - \vec{h}_i|/c$ which is just the timing residual $t_{\text{residual}}$ of Equation 2.1 with added $t_0$. The sums are over all hits.

The hit pattern goodness allows us to identify Cherenkov events by their azimuthal-symmetric ring pattern from a reconstructed vertex and direction. All others are labeled mis-reconstructed or non-Cherenkov events. A goodness function $g_p(\vec{v})$ is defined for all directional events.

A cut on the goodness values is made in tandem using a hyperbolic radius of $g_t^2 - g_p^2 > 0.25$ and rejecting all other events. Figure 9 shows this background reduction cut on data and $^8$B Monte Carlo in the 7.0-7.5 MeV bin. When the cut is applied to LINAC data and MC, a total flux systematic error of $\pm 3.0\%$ is obtained.

The timing-hit pattern cut is treated as a second reduction after the removal of noise and spallation events from the initial data set. All cuts and their efficiencies are shown in Figure 10.
FIG. 7: Top left: Deviation in energy scale between LINAC MC and data. Bottom left: differences in energy resolution between LINAC MC and data. Refer to Figure 6 to relate data points with tank positions. Top right: $^{16}$N energy scale deviation from MC. Representing the varying times calibration data were taken, (1) Nov. 2003, (2) March 2004, (3) July 2004, (4) Nov. 2004, (5) Sep. 2005. (a), (b), and (c) represent the x positions 15.20 m, 10.96 m, −14.49 m respectively. All other calibration data were taken at x = 0.35 m. Bottom right: $^{16}$N energy scale deviation from MC for 6 selected zenith angles of the detector (-1 is down).

FIG. 8: Trigger efficiency as a function of energy. The black dots are $^{16}$N calibration data and the lines are the best-fit error functions to the data (red solid is LE and green dashed is SLE).

C. Total Flux Result

The SK-II solar neutrino signal is extracted from the strongly forward biased direction of recoil electrons from $\nu$-e elastic scattering. A likelihood fit to the signal and background is utilized to determine the flux. For a live time of 791 days of SK-II data from 7.0 to 20.0 MeV, the extracted number of signal events is $7212.8^{+152.9}_{-150.9}$ (stat.)
+483.3^{+4.2}_{-3.9} (sys.). The corresponding $^8$B flux is:

\[(2.38 \pm 0.05 \text{(stat.)} ^{+0.16}_{-0.15} \text{(sys.)}) \times 10^6 \text{ cm}^{-2}\text{sec}^{-1}.\]

It is statistically consistent with the SK-I value of \((2.35 \pm 0.02 \text{(stat.)} \pm 0.08 \text{(sys.)}) \times 10^6 \text{ cm}^{-2}\text{sec}^{-1}\). The systematic uncertainties of SK-I and II are mostly uncorrelated due to differences in energy scale, event selection, event reconstruction methods, etc. Figure 11 shows the angular distribution of extracted solar neutrino events. Table I lists the SK-II systematic errors assigned for the total flux and day-night difference.

TABLE I: SK-II systematic error of each item in %. Numbers in parentheses are the values obtained from calibration data before application to the neutrino flux.

| Item                        | flux     | day-night |
|-----------------------------|----------|-----------|
| Energy scale (absolute ±1.4%) | +4.2 - 3.9 | ±1.5     |
| Energy scale (relative ±0.5%) | ±0.3    |           |
| Energy resolution (2.5%)    | ±0.3    |           |
| $^8$B spectrum              | ±1.9    |           |
| Trigger efficiency          | ±0.5    |           |
| 1$^{st}$ reduction          | ±1.0    |           |
| 2$^{nd}$ reduction          | ±3.0    |           |
| Spallation dead time        | ±0.4    |           |
| Gamma cut                   | ±1.0    |           |
| Vertex shift                | ±1.1    |           |
| Non-flat background         | ±0.4    | ±3.4     |
| Angular resolution (6.0%)   | ±3.0    |           |
| Cross section               | ±0.5    |           |
| Live time                   | ±0.1    | ±0.1     |
| Total                       | +6.7 - 6.4 | ±3.7     |

FIG. 10: Summary of the data reduction steps (top) and their efficiencies on MC (bottom)

FIG. 11: The angular distribution of solar neutrino candidate events. The flat line seen under the peak in the solar direction represents background contributions.

D. Time Variation Results

1. Day-Night and Seasonal Variation

Time variations of the solar neutrino flux are also determined by looking at day and night fluxes and the change in total flux at regular intervals during the live time of SK-II. The day and night fluxes are measured by selecting events which occur when the cosine of the solar zenith angle is less than zero (day) and greater than zero (night). Unlike the total flux, the day and night fluxes are quoted using a threshold of 7.5 MeV due to low signal to noise ratio for the 7.0-7.5 MeV bin in the solar
direction after the data set is divided. Their values are
\[ \Phi_{\text{day}} = (2.31 \pm 0.07\text{(stat.)} \pm 0.15\text{(sys.)}) \times 10^6 \text{ cm}^{-2}\text{sec}^{-1}, \]
\[ \Phi_{\text{night}} = (2.46 \pm 0.07\text{(stat.)} \pm 0.16\text{(sys.)}) \times 10^6 \text{ cm}^{-2}\text{sec}^{-1}. \]

With these fluxes, the asymmetry value is found from
\[ A = (\Phi_{\text{day}} - \Phi_{\text{night}}) / \left( \frac{1}{2}(\Phi_{\text{day}} + \Phi_{\text{night}}) \right). \]

The SK-II day-night difference yields
\[ A = -0.063 \pm 0.042\text{(stat.)} \pm 0.037\text{(sys.)}. \]

As with SK-I (\( A = -0.021 \pm 0.020\text{(stat.)}^{+0.013}_{-0.015}\text{(sys.)} \)), no day-night asymmetry is discerned from the SK-II solar data set. The SK-I asymmetry value is statistically consistent with SK-II.

The total flux variation as a function of time, or seasonal variation, for both SK-I and SK-II solar data is shown in Figure 12. Each bin represents 1.5 months and is seen to follow a sinusoidal trend consistent with the expected \( 1/r^2 \) flux variations due to the eccentricity of the earth's orbit around the sun. Errors are statistical only. The absence of data points between SK-I and SK-II indicates dead time while construction of SK-II was occurring.

The recoil electron energy spectrum is obtained by dividing the total flux into 17 energy bins ranging from 7.0 to 20.0 MeV. The bin boundaries and flux values are listed in Table II. Figure 14 shows the observed energy spectrum divided by the expected spectrum without oscillation determined from the BP2004 SSM [4]. The line through the spectrum represents the total SK-I 1496-day average. Again, as with the seasonal variation, SK-II shows excellent agreement with SK-I.

IV. SK-II OSCILLATION ANALYSIS

A. \( \chi^2 \) Minimization

Oscillations of solar neutrinos have been studied by numerous experiments and have placed increasingly strin-
TABLE II: SK-II observed energy spectra expressed in units of event/kton/year. The errors in the observed rates are statistical only. The 7.0-7.5 MeV energy bin is excluded from the day-night analysis. Correction is made for the reduction efficiencies. The best fit values are given in the LMA region. \( \theta \) is the angle between the z-axis of the detector and the vector from the Sun to the detector.

| Energy (MeV) | ALL | Observed rate | Expected rate |
|-------------|-----|---------------|---------------|
|             | DAY | NIGHT \( 0 < \cos \theta \leq 1 \) | \( 8B \) | hep |

FIG. 14: Ratio of observed and expected energy spectra. The purple lines represent a ±1 sigma level of the energy correlated systematic errors. The black line represents SK-I 1496-day average and shows agreement with SK-II.

The determination of the solar neutrino oscillation parameters \((\theta_{12}, \Delta m^2)\) in SK-II is accomplished in much the same way as the previous SK-I result. Two neutrino oscillation is assumed and for each set of oscillation parameters, a \( \chi^2 \) minimization of the total \( 8B \) and hep neutrino flux is fit to the data. The entire SK-II observed spectrum is utilized from a 7.0 MeV threshold. The expected oscillated \( 8B \) and hep flux is derived from numerically calculated MSW [9] \( \nu_e \) survival probabilities and the unoscillated flux provided by the SSM. It is then converted to an expected SK-II rate spectrum by utilizing the \( \nu - e \) elastic scattering cross section and the SK-II detector’s energy resolution. To account for the systematic uncertainties in energy resolution as well as the energy scale and the \( 8B \) neutrino spectrum model shape, the combined rate predictions are modified by energy shape factors, \( f(E_i, \delta B, \delta S, \delta R) \). \( \delta B, \delta S, \) and \( \delta R \) represent uncertainty in the \( 8B \) neutrino spectrum, SK-II energy scale, and SK-II energy resolution respectively. The function \( f \) serves to shift the rate predictions corresponding to a given uncertainty \( \delta \) in the data rate. The following equation shows the SK-II spectrum \( \chi^2 \) along with energy correlated systematic error shape factors applied to the expected rate:

\[
\chi^2_{SK-II} = \sum_{i=1}^{17} \frac{(d_i - (\beta b_i + \eta h_i) \times f(E_i, \delta B, \delta S, \delta R))^2}{\sigma_i^2} + \sum_{j=1}^{17} \frac{(d_j - (\beta b_j + \eta h_j))^2}{\sigma_j^2}
\]
where \( d_i \) is the observed rate divided by the expected, unoscillated rate for the \( i^{\text{th}} \) energy bin. Similarly, \( b_i \) and \( h_i \) are the predicted MSW oscillated rates divided by the unoscillated rate for \(^8\text{B}\) and hep neutrinos respectively. \( \beta (\eta) \) scales the \(^8\text{B}\) (hep) neutrino flux. The last term is the unbinned time-variation likelihood to the SK-II solar zenith angle flux variation above a 7.5 MeV threshold. This likelihood is analogous to the one used in SK-I.

The energy uncorrelated systematic uncertainty is assigned to 4.8\% (the quadrature sum of the energy independent errors in Table I) and is used to describe the error on the total rate. For the spectrum rate uncertainties, the value 4.8\% is conservatively assigned to each bin and is added in quadrature to the statistical error (Table II) to equal \( \sigma_\epsilon \) in the SK-II \( \chi^2 \). See the appendix of 11 for more details.

### B. Oscillation Results - SK Only

A minimization of the \( \chi^2 \) in the previous section yields excluded regions when \( \beta \) and \( \eta \) are left unconstrained. By constraining the \(^8\text{B}\) flux to the total NC flux value from SNO 12, allowed parameter regions can be obtained. Figure 15 shows both excluded and allowed regions at 95\% confidence level. They are consistent with previous SK-I results. The primary constraint in SK-II is from the time-variation data although some spectral exclusion is also seen at \( \Delta m^2 \approx 10^{-4}\text{eV}^2 \). The same oscillation analysis is performed while including \( \chi^2 \) terms corresponding to the SK-I values (namely, the spectrum and unbinned time variation for SK-I). In this combined analysis, SK-II helps expand the 95\% c.l. exclusion from the SK-I-only analysis, mostly along a region dominated by the spectral constraint (\( 10^{-1} < \tan^2 \theta < 0.4 \) and \( 4 \times 10^{-5}\text{eV}^2 < \Delta m^2 < 2 \times 10^{-4}\text{eV}^2 \)). However, when constraining \(^8\text{B}\) to the SNO NC flux, the SK allowed regions are largely unaffected by the addition of SK-II data.

### C. Oscillation Results - SK and Other Solar Experiments

The combination of other solar neutrino experiments such as the SNO and radiochemical results with the SK combined analysis is accomplished by fitting the total CC and NC rates observed by SNO’s 306-day pure \( \text{D}_2\text{O} \) 13 and 391-day salt phases 12. Also, the SNO NC constrained predicted day-night asymmetry for the pure \( \text{D}_2\text{O} \) phase is used for added exclusion power. The radiochemical experiments of Homestake, GALLEX, and SAGE 14 are then added using the best \(^8\text{B}\) and hep fluxes from the SK-SNO fit. Figure 15 shows the combined solar allowed areas. The best fit parameter set is \( \tan^2 \theta = 0.40 \) and \( \Delta m^2 = 6.03 \times 10^{-5}\text{eV}^2 \) consistent with the SK-I global analysis.

### V. CONCLUSION

Super-Kamiokande has measured the solar \(^8\text{B}\) flux to be \((2.38 \pm 0.05\text{(stat.)}^{+0.10}_{-0.15}\text{(sys.)}) \times 10^6\text{cm}^{-2}\text{sec}^{-1}\) during its second phase. The uncertainties in SK-II are larger than in SK-I but a low analysis threshold of 7 MeV was achieved (7.5 MeV in the day-night variation analysis). A day-night asymmetry value was observed to be \(-0.063 \pm 0.042\text{(stat.)} \pm 0.037\text{(sys.)}\) which is consistent with zero and the result from SK-I. SK-II has brought the total SK time-dependent flux measurement to a length of 9.5 years and this measurement is compared with solar activity in solar cycle 23 resulting in no strong correlation. In the combined SK-I and SK-II global oscillation analysis, the best fit is found to favor the LMA region at \( \tan^2 \theta = 0.40 \) and \( \Delta m^2 = 6.03 \times 10^{-5}\text{eV}^2 \), in excellent agreement with previous solar neutrino oscillation measurements. SK-I and SK-II agree well, showing no evidence of any systematic effects from the introduction of new methods, blast shields, reduced PMT coverage, etc.

### Acknowledgments

The authors gratefully acknowledge the cooperation of the Kamioka Mining and Smelting Company. Super-K has been built and operated from funds provided by the Japanese Ministry of Education, Culture, Sports, Science and Technology, the U.S. Department of Energy, and the U.S. National Science Foundation. This work was partially supported by the Korean Research Foundation (BK21), the Korean Ministry of Science and Technology, and the National Science Foundation of China.
FIG. 15: The left plot shows SK excluded areas. The purple region is SK-II and the light blue region is SK-I with SK-II. The black line shows SK-I only, and evidence of increased exclusion can be seen with the addition of SK-II data. The center plot shows SK allowed regions (same representative colors as the exclusion contours) with the $^8$B flux constrained to the SNO total flux measurement. The hep flux is a free parameter. The right plot shows the SK-I and SK-II combined contour with SNO and radiochemical solar experimental data (blue contour). The green contour is the KamLAND [15] electron anti-neutrino oscillation result.
