Dear editor,

Please find attached the revised manuscript and supplementary material of the manuscript « A new dataset of soil Carbon and Nitrogen stocks and profiles from an instrumented Greenlandic fen designed to evaluate land-surface models » by X. Morel, B.U. Hansen, C. Delire, P.L. Ambus, M. Mastepanov and B. Decharme.

All the remarks, minor and major comments made by the different reviewers have been carefully addressed, and point-by-point responses to each of the eight reviewers have been posted in the interactive discussion.

As some additional minor rephrasing and rewriting have been done following the inputs of professional English writers, it is possible than some English corrections addressed to reviewers concerning the English text have been modified since responses to reviewers have been made.

Here are listed the major changes addressed to the manuscript :

- A thorough check of scientific English use.
- A rewriting of the abstract and introduction following reviewers comments.
- In particular, we added paragraphs on greenlandic fens characteristics and on the lack of nitrogen data, as asked by reviewer #7.
- According to reviewer #7, manuscript have been rewritten by putting an emphasis on Nitrogen stocks, neglected in the first version of the paper. Two subsections have been added in the Results concerning nitrogen stocks and profiles.
- Figure 1 is improved by adding coordinates, proper length bars, compass roses, and highlighting zones of interest of the fen (automatic chambers, flux tower, soil temperature probes)
- Methods and Materials section has been fully reorganized according to ESSD criterions and some reviewers comments to improve the logical flow and readability of the paper
- Same for Results section.

We want to thank the different reviewers for their inputs that greatly helped improving the manuscript quality, and we hope the changes made will convince the reviewers and the editors that the manuscript reached sufficient quality for publication.

Best regards,

Xavier Morel
A new dataset of soil Carbon and Nitrogen stocks and profiles from an instrumented Greenlandic fen designed to evaluate land-surface models

Abstract. Arctic and boreal peatlands play a major role in the global carbon (C) cycle. They are particularly efficient at sequestering carbon due to their high water content which makes primary productivity exceed decomposition rates. Though, because their high water content limits decomposition rates to levels below their net primary productivity. Their future in a climate-change context is quite uncertain in terms of carbon emissions and carbon sequestration.

Nuuk-fen site is a well-instrumented greenlandic site of particular interest for testing and validating land-surface models, with monitoring of soil physical variables and greenhouse gas fluxes (CH₄ and CO₂) and is of particular interest for testing and validating land-surface models. But knowledge of soil carbon stocks and profiles is missing. This is a crucial shortcoming for a complete evaluation of models, as soil carbon is one of the primary drivers of CH₄ and CO₂ soil emissions. To tackle this issue, we measured for the first time soil carbon and nitrogen density, profiles and stocks in the Nuuk peatland at the exact location of fluxes monitoring (64°07.51”N, 51°23’10”W), colocated with the greenhouse gas measurements. Measurements were made along two transects. Measurements horizontal resolution is 60 and 90 m long and with a horizontal resolution of 5 meter, vertical resolution ranges from 5 to 10 cm. Mean soil carbon density is 50.2 kg C m⁻³ using a 4 cm diameter gouge auger. 135 soil samples were analyzed. Soil carbon density varied between 6.2 kg C m⁻³ to 160.2 with a mean value of 50.2 kg C m⁻³. Mean soil nitrogen density was 2.37 kg N m⁻³. Mean soil carbon and nitrogen stocks are 36.3 kg C m⁻² and 1.7 kg N m⁻². These new data are in the range of those encountered in other arctic peatlands. This new dataset, one of very few in Greenland, can contribute to further developing joint modelisation development of joint modeling of greenhouse gas emissions and soil carbon and nitrogen in land-surface models. The dataset is open-access and available at https://doi.org/10.1594/PANGAEA.909899.
1 Introduction

The terrestrial biosphere plays an important role in regulating atmospheric greenhouse gas composition and climate by greenhouse gas exchanges and its capacity to act as a carbon sink (Friedlingstein et al., 2019). For instance, northern latitudes wetlands account for one third to one half of the methane emissions from natural wetlands (Schlesinger and Bernhardt, 2013). Of all these, among all terrestrial ecosystems, peatlands are arguably the most efficient at sequestering carbon (C) over long time scales (Loisel et al., 2014; Leifeld and Menichetti, 2018). Peatlands are a particular type of wetlands, permanently saturated, and occur for permanently saturated wetlands, and cover 3% of terrestrial surface the global land surface (Xu et al., 2018). In these ecosystems, the anaerobic conditions due to the created by high water content lead to slow carbon decomposition. The accumulation rate of organic matter is hence higher than its decomposition rate. Due to their high productivity and/or slow decomposition, peatlands are consequently an important long-term soil carbon reservoir: their estimated carbon storage ranges between 550 and 694 GtC (Yu et al., 2010; Yu, 2012) (Gorham, 1991). When undisturbed, these ecosystems are a net sink for atmospheric CO$_2$ attributed to (Jungkunst et al., 2012).

Thus, peatlands (Jungkunst et al., 2012). Peatlands have consistently sequestering C although at variable rates throughout the entire Holocene period (Yu et al., 2011). Globally they are estimated to store between 550 and 694 GtC, about a third of global soil organic carbon stocks (Yu et al., 2010; Yu, 2012). Peatlands play a major role in the global carbon cycle (Harenda et al., 2018). During the Holocene, as peatland C sequestration is strongly correlated with atmospheric CO$_2$ concentration (Yu et al., 2011). As for the terrestrial carbon cycle, recent evidences suggest a significant shift of originally permafrost stored carbon onto peatlands (Lindgren et al., 2018) during the same period. But their (Harenda et al., 2018; Limpens et al., 2008).

Their future in a climate-change context-changing climate is quite uncertain, in terms of carbon emissions magnitude and carbon the magnitude of carbon emissions and sequestration (Yu et al., 2011).

Recent studies suggest that peatlands will remain a carbon sink in the future, although their response to global warming will switch from a negative to a positive feedback (Gallego-Sala et al., 2018). As natural carbon fluxes from and to terrestrial reservoirs are annually an order of magnitude larger than perturbation from land use change and fossil emissions (Schuur et al., 2008); large positive feedback from land biomass and soils on the atmospheric carbon pool may be triggered by a temperature increase. As peatlands organic matter accumulation rate depends not only on soil moisture but also on other factors such as soil temperature, net primary production (NPP), soil solar irradiance, air temperature, vegetation type, etc., many complex feedbacks may occur in the future. A direct feedback of climate warming on microbiological activity and, therefore, enhanced organic matter decomposition and greenhouse gas emissions from soil is indeed highly probable. On the other hand, higher temperature leads to higher evapotranspiration which eventually leads to dryer conditions that may hamper decomposition despite the better temperature condition. Changes in soil moisture is also known to alter the soil moisture, soil temperature, soil carbon and soil nutrient content, all of which depend on climate. To be able to estimate how much litter and soil carbon might be decomposed, it is necessary to know the carbon stock at present time. It is also important to know its
vertical profile in the soil because the decomposition rate and ratio of $CH_4$ to $CO_2$ ratio production:production depend on depth through soil temperature and soil moisture vertical profiles.

In these regions, knowledge of carbon-Nitrogen (N) is a limiting factor for plant growth and microbial activity in northern soils (Vitousek and Howarth, 1991) and could play an important role in future northern land carbon storage (Kicklighter et al., 2019) and greenhouse gas emissions (Luan et al., 2019). Increased nitrous oxide release from northern soils with permafrost thaw have been reported (Elberling et al., 2010; Voigt et al., 2017). However, very little is known on nitrogen stocks in these soils.

Knowledge of carbon and nitrogen stocks and profiles is hence particularly important. In the last decades, a growing number of sites in the arctic and boreal regions were instrumented in order to measure the greenhouse gas emissions of these ecosystems—such as Abisko in Sweden (Jammet et al., 2017), Samoylov in Russia (Siewert et al, 2015, 2016) or Zackenberg in Greenland (Pirk et al., 2016, 2017) (see Table 1). Similarly, more and more measurements of soil carbon stocks and profiles are conducted every year. Unfortunately, although large scale soil carbon databases already exist (e.g HWSD (FAO et al., 2012) or NCSCD (Hugelius et al., 2013)) the Harmonized World Soil Database (FAO et al., 2012) or the Northern Circumpolar Soil Carbon Database (Hugelius et al., 2013), very few sites measure both the greenhouse gas fluxes together with have both greenhouse gas flux and soil carbon content measurements (see Table 1). This is a substantial shortcoming that needs to be addressed, as carbon profiles are one of the primary drivers for of $CO_2$ and $CH_4$ production and emission (Raich and Schlesinger, 1992). Moreover, for the few sites where soil carbon for which soil carbon stocks and greenhouse gas fluxes are available, both are quite often not measured at the same location (sometimes more than a few kilometers apart). Due to fine-scale heterogeneity (vegetation, microtopography, etc...), they may reflect completely different functioning conditions (e.g. first datasets from Zackenberg site (Sigsgaard et al., 2007; Palmtag et al., 2015)). For From a site-scale modeling point-of-view, it is then important to get fluxes therefore important to have greenhouse gas flux data (e.g. $CH_4$ and $CO_2$) and state variable data (C stocks and profiles) as close as possible available at the same locations.

There are many challenges accompanying the joint modelisation of greenhouse gas emission to simultaneously modeling greenhouse gas emissions and soil carbon in land-surface models. For instance, Chadburn et al. (2017) noted that models that currently get simulate realistic soil temperature and soil carbon currently produce unrealistically low methane fluxes. It appears therefore necessary to improve the coupling of biogeochemical and physical processes of land-surface models. An example of recent attempt in this direction attempts at this is the biogeochemical carbon and greenhouse gas emissions model presented in Morel et al. (2019a) and embedded in the land surface model Interaction Soil-Biosphère Atmosphère Soil-Biosphère-Atmosphere (ISBA; Noilhan and Planton (1989)). Although the biogeochemical and physical part of this model has been validated on three distinct boreal and arctic sites, the lack of soil carbon data did not allow a complete evaluation of this model. Hence, we conducted field experiments—a field experiment in a well-instrumented greenlandic peatland, Nuuk-fen, to collect soil carbon stocks and profiles data. Carbon sampling localisations are in the same spot as at the location of the
automatic chambers measuring $CH_4$ and $CO_2$ fluxes and along two transects.

There is very little data available on wetlands in Greenland in general and fens in particular due to logistical difficulties to reach them. Fen extent in Greenland was recently estimated using a combination of remote sensing data and ground measurements (Karami et al., 2018). They find the extent of fen to be 4461 km$^2$, about 1.4% of the ice-free area and 5% of the vegetated area of Greenland. In terms of in-situ data, (Palmtag et al., 2015, 2018) sampled a few fens for soil carbon and nitrogen in the Zackenberg valley. Barthelmes et al. (2015) in their review only list a dozen published in-situ measurements of peat deposits (both active and inactive), fairly shallow (less than 1 m) for the active ones. Among those, only 2 deal with carbon fluxes or stocks (MacDonald et al., 2006; Horwath Burnham and Sletten, 2010), the others being mostly paleoecological and archeological studies. Except for (Palmtag et al., 2018), none include nitrogen data. Hence, a new dataset on carbon and nitrogen content of a Greenland fen is important.

The aim of this paper is to present and validate a new dataset of soil carbon and nitrogen stocks and profiles from an instrumented greenlandic fen, Nuuk-fen. In Section 2 we present the Kobbefjord site, in particular the fen’s physical characteristics and specificities. We present in Section 3 the experimental protocol and the methods of the field and laboratory studies. Section 4 presents collected data of soil bulk density, water content, soil carbon content, profiles and stocks, as well as nitrogen and carbon/nitrogen (C/N) ratios. Finally, we discuss the dataset robustness and interests in Section ?? possible uses. These soil carbon and nitrogen data will complement the existing dataset of greenhouse gas fluxes from the fen. The combined dataset will allow to evaluate the fluxes and stocks simulated by land-surface models in a completely consistent manner. The dataset is open-access and available at https://doi.org/10.1594/PANGAEA.909899 (Morel et al., 2019b).

2 Site presentation

**Study Area**

**Nuuk Research Station** The studied fen (Nuuk-fen) is located within the Nuuk Ecological Research Station and is part of the Greenland Ecosystem Monitoring program, which provides detailed reports on an annual basis, dating back to 2007 for Nuuk (Nuuk Ecological Research Operations - NERO - Annual reports ; Tamstorf et al. (2008)). The site Research Station is well-instrumented and participates to in several research programs, ranging from studying the dynamics of organisms and biological processes, the physical characteristics of marine, coastal and terrestrial environments, and performing climate and hydrology monitoring as well. Related data are public and open access on the Greenland Ecosystem Monitoring database repository, to be found at http://data.g-e-m.dk/.

Located in the sub-Arctic, Nuuk Research station is located in the southwest of Greenland. Nuuk research station does not have any permafrost (Geng et al., 2019). It is situated in Kobbefjord (64°07’N ; 51°21’W), approximately 20 km from Nuuk. The study area It is not in the permafrost region (Geng et al., 2019). According to the classification of Glooschenko et al. (1993) of Arctic and Subarctic wetlands, Nuuk fen is in the Low Subarctic Wetland Region. The research station consists of a drainage
basin of 32 square kilometers $km^2$ situated at the head of a fjord. The local climate is low arctic sub-Arctic with mean annual temperature of $-1.4^\circ$C and mean annual precipitation of 752 mm (1961-90). Despite cold winter temperatures, the fen never freezes at depth below 10 – 15 cm. NERO annual reports (Tamstorf et al., 2008; Raundrup et al., 2010) show a significant variability in soil texture, soil moisture, vegetation and microtopography. The studied zone, the only fen of the fjord, is surrounded by high rocks (left-top panel of Figure 1). The fen is located between the fjord and the Bade So lake. Datings of the sedimentary layer of Bade So (Larsen et al., 2017) showed that the lake was under sea level until 8500 BP. Hence, the fen can not be older. The underlying geology of the parent material is bedrock composed of Archaean tonalitic to granodioritic gneiss, and Qorgût granite (Larsen et al., 2017).

The fen is instrumented with automatic chambers and an eddy flux tower, both of particular use and a regular automated weather station, particularly useful for land-surface models. Soil temperatures are also monitored at different depths in the fen. There are no continuous water measurements devices, but some isolated water table depth measurements are occasionally made throughout the year (Raundrup et al., 2010).

Due to its topographical specificity, Nuuk CO$_2$ and CH$_4$ automatic chamber flux measurements started in 2007 and are still ongoing. The chambers usually operate from mid-May to mid-October. Each year, the main input of water on this site is not from the local precipitation, but CH4 flux peaks in July/August with values around 6 mg CH$_4$.m$^{-2}$.h$^{-1}$, and declines to about half of the maximum in early September. Peak CO$_2$ fluxes happen end of July - early August, reach about $-300$ mg CO$_2$.m$^{-2}$.h$^{-1}$, and occur at the peak of the growing season when photosynthesis is a much larger flux than soil respiration. These fluxes are described in Pirk et al. (2017); Morel et al. (2019a).

The main water inputs to the fen are from snowmelt and runoff from adjacent hills and inflow from a nearby stream located at the southern border of the fen (bottom panel of Figure 1). One key factor of this site appears to be the snowmelt date, as snowmelt water runs through the fen, leading to saturated moisture conditions during the growing season. We show that the darker areas in the center roughly correspond to the wetter areas. In these zones, the vegetation is adapted to saturated conditions. This vegetation for instance, the albedo is lower at the center has a lower albedo than in the fenfronters’s outer area, thereby absorbing more solar radiations to compensate the colder conditions. Figure 2 shows the different vegetation types encountered throughout the fen, going from green herbaceous species and mosses in the outer part aquatic plants dotted and aquatic plants with aerenchymas and Sphagnum in the center of the fen. Section 3.1 explains more precisely these differences in vegetation.
3 Methods-Material and material Methods

All the measurements were made in July 2017 along two transects, shown in the bottom panel of Figure 1. Each transect was sampled every 5 meters, thus defining the plots T1 – 0, T1 – 5, T1 – 10 and so on.

The first transect (T1) roughly follows a N-S axis. The automatic chambers are situated on either side of the transect between plots T1 – 0 and T1 – 20. The second transect (T2) starts at the last automatic chamber, at the 20 meter plot of the first transect, in the middle of the fen and goes through the fen in its larger axis. The soil temperature probes can be seen between plots T2 – 30 and T2 – 45.

3.1 Physical-site measurement Fen physical characteristics

First, we investigated the topography of the fen and the depth of the sediment layer that delimits organic and mineral soil horizons at every plot for both transects. The elevation was measured with a topographer rod. The depth of the organic-mineral interface (OMI) was measured with a rigid metallic probe. The probe was lowered into the ground until a strong resistance, characteristic of mineral soils, was encountered.

The first transect clearly indicates an accumulation basin at the center of the fen: while the ground elevation remained approximately constant, the OMI depth strongly increased between plots T1 – 0 and T1 – 30 T1 – 25 (Figure 3). This depression is characteristic for peatlands formation, and contributes to organic material accumulation and burial in these ecosystems. Its maximal depth, of approximately 1 meter, is situated at T1 – 30 was situated at T1-25 , and roughly corresponds to the darker part of the fen surface (Figure 1) and standing water (Figures 3.a and 2.b). The OMI depth sharply increases in less than 10 meters then stays increased in 15 meters, then stayed relatively stable. The plot T1 – 40 seems to mark the end of the fen. In this intermediate area from T1 – 40 to T1 – 60, surface moisture conditions are much dryer were much drier (Figure 2.d) and the vegetation did not consist of aquatic plants such as Sphagnum anymore. Green herbaceous and mosses became then predominant. After the extinction of the fen, hummocky topography appears (relief characterized by T1 – 40 to T1 – 60 are characterized by a hummocky topography (little mounds and depressions). The that cannot be picked up by 5 meters resolution of measurement does not allow to distinguish these relief.

The second transect started at the 20 meter plot of the first transect (T2 – 0 = T1 – 20), in the middle of the fen. Until plot T2 – 30, the soil elevation and the OMI depth did not vary much. There is a peak in the OMI depth at T2 – 45, surrounded by two small depressions, while the soil elevation lowered. The end of the transect matches with the limit of the fen and. Approaching this boundary, the soil elevation and the mineral layer both rises.
3.2 Soil carbon sampling along the transects

Soil samples were taken every 5 meter along the first transect between from the plots T1 – 0 and to T1 – 35, as we focused solely on the peat deposit. As the second transect fully lay in the peat deposit, we sampled its full length with a soil samples were taken every 10 meter distance between m for the whole transect, i.e. between the plots T2 – 0 and T2 – 80.

Samplings were made using a manual gouge auger, with double spade grip and a cylindrical semi-open soil focused on the peat deposit. As the second transect fully lay in the peat deposit, we sampled its full length with a soil samples were taken every 10 meter distance between m for the whole transect, i.e. between the plots T2 – 0 and T2 – 80.

Samples were then extracted along the full soil core at regular intervals: every 5 cm in the top 15 centimeters, every 10 cm below. Soil samples were individually stored in small sealed plastic bags just after extraction in order to limit oxygen exchanges and halt decomposition.

Ideally, soil samples should be stored at a 4°C temperature before being transferred to the lab. With no fridge on the site, we used an insulated cooler in order to control at best the samples’ temperature. The maximum elapsed time between sample collection and their deposit at the laboratory was 3 days. Hence, three days. Although the temperature control of the samples may not have been optimal, this short delay between sample collection and handling prevented any significant decomposition.

3.3 Soil samples handling and analysis

Soil samples (n = 135) were first analyzed in the Greenland Institute at the Greenland Institute of Natural Resources, located in Nuuk. For each sample, volume and mass were carefully measured following the method of Chambers et al. (2010) by removing a known-volume sample of peat using a volumetric sampler, measuring it again with a 0.1 mm precision vernier, and weighing it in a crucible in order to determine the density of the gross sample density $\rho_{sample}$ (g.m$^{-3}$).

Despite a careful measurement and a method designed to limit sample compaction, we recognize that some uncertainties on the samples densities are difficult to quantify:

1. The act of measurement and the soil core extraction can compress the samples within the manual gouge auger, hence modifying their structure.

2. Extracting the samples from the water-saturated soil layers without loss of water is obviously challenging, hence modifying the sample total mass. This potential loss of water can also change the available space within the soil pores, making the sample potentially more sensitive to any compaction.
3. The almost-liquid texture of the water-saturated samples makes it difficult to measure the sample volume. For these water-saturated samples, we used known volumes vials for volume measurements instead of the 0.1 mm precision vernier.

Peat samples were then oven-dried at 80 °C during for 48 hours to ensure until a constant weight was reached (Djukic et al., 2018). Figure 4 shows samples at different depths for the soil cores T1 – 10 and T1 – 25 after drying. The samples of the T1 – 10 soil core present a well-marked color gradient indicating the different soil horizons. For example, the colour and texture of sample 10 – 60/65 (taken at 60 – 65 cm depth) of plot T1 – 10 is characteristic of a mineral soil and corresponds indeed to the OMI (Figure 3). On the contrary, the T1 – 25 soil core (in the center of the fen) did not have any significant gradient of color and texture, except a mixed-appearance sample for a mixed-appearance zone at 60 – 65 cm depth. We show later on that these differences in color could be mainly explained by soil carbon content.

After drying, we determined the mass fraction of water of each sample, noted \( f_{\text{wet}}(\%) \). In order to estimate the carbon density within the soil from the mass percentage per sample dry mass, we need to know the soil bulk density, noted \( \rho_{\text{bulk}} \), defined as the dry mass per unit of total volume (Boelter, 1969; Hossain et al., 2015). The observed bulk density \( \rho_{\text{obs}} \) was computed as:

\[
\rho_{\text{obs}} = \rho_{\text{sample}} (1 - f_{\text{wet}})
\]

(1)

Dried peat samples were then sent to the Center for Permafrost (CENPERM - University of Copenhagen - Denmark) for further C and N analysis. Briefly, 10 mg portions of thoroughly mixed and finely ground sample materials were weighed into tin combustion cups for Dumas combustion (1700 °C) on an elemental analyser (CE 1110, Thermo Electron, Milan). Peat standards (Elemental Microanalysis, Okehampton, UK) were included for elemental analyser mass calibration in order to obtain percentage of C and N content, noted \( f_C \) and \( f_N \) (\%) respectively.

Soil carbon density \( \rho_C \) (\( gC.m^{-3}_{\text{soil}} \)) was then computed as:

\[
\rho_C = \rho_{\text{sample}} f_C (1 - f_{\text{wet}}) = \rho_{\text{bulk}} f_C
\]

(2)

Similarly, soil nitrogen density \( \rho_N \) (\( gN.m^{-3}_{\text{soil}} \)) was computed as:

\[
\rho_N = \rho_{\text{sample}} f_N (1 - f_{\text{wet}}) = \rho_{\text{bulk}} f_N
\]

(3)
4 Results

A total of \( n = 135 \) samples were collected along both transects (\( n_1 = 65 \) and \( n_2 = 70 \)). For each of these samples, values of mass, volume, density, dry mass, bulk density, carbon and nitrogen content (\%) and density (kg.m\(^{-3}\)), and carbon-nitrogen (C/N) ratios were measured and/or calculated. Figure 5 shows distribution histograms for all data, and descriptive statistics (mean, median, upper and lower deciles) are presented in Table 2.

Figure 6 presents mean soil profiles of bulk density, water mass fraction, carbon and nitrogen content and density along both transects.

These soil profiles (\( n = 17 \)) were averaged over depth for both transects and are presented in Figure 7. As the fen depth has showed a substantial variability along the transects, resulting averaged profiles are noisy. For instance, samples extracted at 50 cm depth may be in a very purely organic soil horizon or a quasi-mineral one depending on the fen area it was extracted from. Hence, mean soil profiles do not necessarily reflect the vertical distribution of data with respect to the OMI.

To reduce the noise due to the OMI heterogeneity, we renormalized all the data with respect to the OMI. For a sample extracted at a depth \( z \) from a peat core with an OMI depth \( z_{OMI} \), we define its normalized distance from OMI \( d_{OMI} \) as:

\[
d_{OMI} = \frac{z}{z_{OMI}} \times 100
\]

These normalized profiles are shown in the figure 8.

For each peat core, total carbon stocks \( C_T \) (kgC.m\(^{-2}\)) were calculated by vertically integrating carbon density profiles using the trapezoidal rule:

\[
C_T = \sum_j (z_{j+1} - z_j) \frac{\rho_{C,j+1} + \rho_{C,j}}{2}
\]

with \( z_j \) the sample depth and \( \rho_{C,j} \) the soil carbon density, computed using equation (2).

Similarly, total nitrogen stocks \( N_T \) (kgN.m\(^{-2}\)) were computed as:

\[
N_T = \sum_j (z_{j+1} - z_j) \frac{\rho_{N,j+1} + \rho_{N,j}}{2}
\]

with \( \rho_{N,j} \) the soil carbon density, computed using equation (3).

Note that because of the difficulties setting the manual gouge auger substantially below the OMI, the maximum sampling depth varied between the different peat cores. Hence, the integration depth also varied between peat cores. However, the carbon
content below this interface did not exceed 7 % except for two unusual samples (Figure 9) and we can consider that not taking into account the soil horizons below the OMI did not underestimate much the computed total C stocks. Similarly, nitrogen content below the OMI are much lower than in the organic horizons (Figure 8), and not taking them into account did not underestimate much the computed total N stocks.

3.1 Calculation of 95% confidence interval soil profile

The sampling mean most likely follows a normal distribution. Under this hypothesis, for a variable \( X \), the standard error of the mean can be calculated as \( \sigma_{X(z)} = \frac{\sigma(z)}{\sqrt{N(z)}} \) with \( N(z) \) the number of samples collected at a depth \( (z) \) and \( \sigma(z) \) the standard deviation over those samples. The confidence interval at 95% is defined as \( I(z) = X(z) \pm 1.96 \times \sigma_{X(z)} \).}

4 Results and discussion

4.1 Bulk Density

Variation in bulk density is attributable to the relative proportion of organic and inorganic soil particles, and is a reliable indicator of the mineral or organic nature of a soil. More than 50% of the samples have a bulk density below 0.187 g.m\(^{-3}\) (Figure 5), characteristic of organic-rich material. Samples with bulk density between 0.5 and 1 g.cm\(^{-3}\) correspond to mixed organic-mineral material (Loisel et al., 2014). The higher the bulk density, the higher the mineral content. Finally, the 10% remaining samples with bulk densities higher than 0.978 g.cm\(^{-3}\) (Table 2) correspond to the most mineral part of the soil with the highest mineral fraction, near or below the OMI, as most mineral soils have bulk densities between 1.0 and 2.0 g.cm\(^{-3}\) (Rezanezhad et al., 2016).

Strong vertical gradients in bulk density can be seen throughout both transects (Figure 6.a). The measured OMI depth delimits well the transition between organic and mineral material, as it should be expected.

Typical bulk density profiles in peatlands tend to show a gradual increase with depth Quinton et al. (2000) (Quinton et al., 2000): as peat decomposition reduces the proportion of large pores by breaking down plant debris into smaller fragments (Rezanezhad et al., 2016), it increases the mass of dry material per volume of peat. Normalized mean profiles of bulk density (Figure 8.b) clearly shows this abrupt transition from mixed organic-mineral material to fully mineral soil below the OMI.

4.2 Carbon mass percentage

Figure 6 shows mass percentage of carbon in the dry samples along the two transects. They can approach reached 50 % (Figure 6.c), which is coherent with the proportions data given in Yu (2012).

As expected, concentration of soil organic carbon in the organic layer is much higher than in the mineral horizons. High
carbon content in the depth of the first transect seems to indicate a carbon burial in the natural accumulation basin. We also note that the limit between the soil horizons with high carbon content and low carbon content also follows the OMI. In particular, the drop of the sedimentary layer in the first transect is clearly visible, and the variations of the mineral layer of the second transect between $T2 - 30$ and $T2 - 60$ meters as well. Normalized mean carbon content profiles (Figure 8.e) clearly show the abrupt decrease in carbon content near the OMI. Below the OMI, carbon contents value are below 10%, which is coherent with the mineral characteristics of the soil horizons below.

5 4.3 Soil carbon density and soil carbon profiles

More than 70% of the soil samples have had soil carbon densities comprised between 20 and 80 kgC.m$^{-3}$ (Figure 5.f). Those values are coherent with those encountered in other arctic and boreal fen and peatlands (Chadburn et al. 2017, Fig.5). Mean local maximum of soil carbon density can reach value up to 80kg.m$^{-3}$ at 80 cm depth (Figure 7.f). One sample has a particularly high carbon density of 160kg.m$^{-3}$ (Figure 9.b). This high value may be due to a bad sample handling during the extraction or manipulation, resulting in a sample compaction that artificially increased measured bulk density.

As expected, soil carbon density matches well the measured organic-mineral interface (Figure 6.e1). The assumed carbon accumulation in the accumulation basin on of the fen discussed in the previous section is confirmed, as a local maximum of soil carbon density is clearly visible at the bottom of the soil plots $T1 - 25$ and $T2 - 30$ (Figure 6.a1).

Mean soil carbon density profiles are non-monotonous. In the organic horizons, SOC density increases with depth and reaches its local maximum between 60 and 80 % of the organic-mineral interface depth (Figure 8.f). Near the OMI, with the abrupt decrease in carbon content and increase in bulk density discussed in the previous sections, the soil carbon density decreases. Soil carbon density profiles that first increases then decreases and then decreased with depth are characteristic of arctic and boreal fens (Chadburn et al. 2017, Fig.5).

4.4 Integrated soil carbon stocks

For each peat core, total carbon stocks $C_T$ (kgC.m$^{-2}$) were calculated by vertically integrating carbon density profiles using the trapezoidal rule:

$C_T = \sum_{j} \left( z_{j+1} - z_j \right) \frac{\rho C_{j+1} + \rho C_j}{2}$

with $z_j$ the sample depth and $\rho C_j$ the soil carbon density, calculated using equation (2).

Note that because of the difficulties setting the manual gouge auger much below the mineral-organic interface, the maximum sampling depth varies between the different peat cores. Hence, the integration depth also varies between peat cores. However, the carbon content below this interface does not exceed 7 % except for two unusual samples (Figure 9) and we can consider that not taking into account the soil horizons below the mineral-organic interface does not underestimate much the calculated total carbon stocks.

11
Tables 3 and 4 presents the carbon stocks and the maximum sampling depth for each peat core along both transects. Mean carbon stocks over both transects is 35.5 kgC m⁻². The review of Yu (2012) on high-latitude fens and peatlands reports integrated soil carbon stocks values between 58.7 and 73.4 kgC m⁻², except one extra extraordinary value of 113.6 kgC m⁻². Those values are higher than those encountered found in Nuuk. But they were computed by considering a fen depth of 1m, which is not the case here. But, the Nuuk fen is quite shallow: the mean sampling depth is often deeper than the OMI does did not exceed 76.3 cm in both transects (Tables 3 and 4). Hence, the results of our soil carbon stocks measurements are then coherent and consistent with current estimates from similar ecosystems.

Finally, a basic estimate of total soil carbon content over the whole fen area is given by multiplying the mean soil carbon mass per unit surface (36.3 kgC m⁻²) by a rough estimate of the fen area (approx. 7500 m², see figure S2). This gives a total carbon storage in the fen of 272 250 kgC.

### 4.5 Soil nitrogen density and soil nitrogen profiles

More than 70% of the soil samples had soil nitrogen densities between 1 and 4 kgN m⁻³ (Figure 5.h), with a mean value of 2.37 kgN m⁻³. The lowest values of N mass indicated the OMI (Figure 6.d). A local maximum of soil N density was clearly visible at the bottom of the soil plots T1 = 25 and T2 = 20 (Figure 6.a1), indicating that nutrients tend to accumulate in the fen basin.

Soil N profiles follow closely the soil C profiles (Figure 7.f.h), indicating a quite uniform C/N ratio through the soil profile (see Section 4.7).

### 4.6 Integrated soil nitrogen stocks

Nitrogen stocks range from 0.8 kgN m⁻² and 2.9 kgN m⁻², with a mean value of 1.7 kgN m⁻² (Tables 3 and 4). This is very similar to the 1.9 ± 0.7 kgN m⁻² value obtained by Palmtag et al. (2018) (Table 2) for the fens on alluvial fans in the Zackenberg valley, to our knowledge the only available in-situ N data for Greenland peatlands.

A basic estimate of total soil nitrogen storage for the whole fen area is given by multiplying the mean soil nitrogen mass per unit surface (1.7 kgN m⁻²) by a rough estimate of the fen area (approx. 7500 m², see figure S2). This gives a total nitrogen storage in the fen of 12 882 kgN.

### 4.7 C/N Ratios

Carbon/Nitrogen-nitrogen (C/N) ratios can give useful information about the nutrient content and the quality and humification degree of organic matter: a low C/N ratio is usually equivalent to a high humification level. With a mean value of 21.6, observed C/N ratios were in the range of those observed from a variety of field and laboratory studies (Bridgham et al., 1998; Rezanezhad et al., 2016; Wang et al., 2015).
C/N ratios were higher in the first few cm depth (approx. 25%), potentially indicating less microbial transformation of the peat in the upper layers (Kuhry and Vitt, 1996). In the greater depth of the fen, C/N ratios were lower because microorganisms slowly consume the carbon and recirculate the nitrogen, resulting in a gradual reduction of C/N values (Rydin and Jeglum, 2013). In northern regions, due to colder temperatures, the decomposition activity is slow, explaining the small difference between maximal and minimal C/N values. The C/N profiles remained relatively stable throughout the depth (21.6%) and the OMI did not seem to distinguish separate zones. Although bulk density and C/N ratios are reliable indicator for peat degradation, the lack of ash content data and isotopic measurements does not allow a quantification of carbon accumulation rate nor carbon loss in the peatland (Krüger et al., 2015).

5 Discussion

4.1 Discussion

Overall, this new dataset of soil bulk density, carbon and nitrogen content, profiles and stocks is in the range of previous estimates (Yu, 2012; Loisel et al., 2014; Chimner et al., 2014).

As noted by Loisel et al. (2014), the accuracy of this type of measurements mostly depends on sample handling, in particular the care deployed to avoid any peat compaction. Our sample density measurements may be uncertain. On the other hand, mass carbon percentages are independent of any compression or any physical alae. And it is known that soil carbon content and bulk density are strongly correlated. For instance, Hossain et al. (2015) noted that bulk density $\rho_{bulk}$ and carbon content $f_C$ follow an exponential relationship:

$$\rho_{bulk} = ae^{-bf_C}$$

with $a = 1.5641$ and $b = 0.0631$.

Figure We find a similar exponential behavior (figure 9) between bulk density and carbon content. The strong correlation discussed in Hossain et al. (2015) is present between bulk density and carbon content with a strong correlation between our measured bulk density and Hossein’s exponential ($r^2 = 0.801$, Table 5). Different types of two-parameters regressions can also be used to infer bulk densities from carbon content, as shown in Table 5. Soil carbon density profiles can hence be computed with two different methods: a "direct" method, using bulk density data (see eq. 2), and an "indirect" method by computing bulk density using carbon content via one of these functional fits. This comparison shows that our measurements of bulk densities are in the right order of magnitude. But these relationships cannot capture the vertical variability of the observed soil carbon profiles. Indeed, mass percentage of carbon $f_C$ (%C) does not encapsulate all the causes of the variability of $\rho_{bulk}$. Consequently, inferred carbon profiles from indirect methods are deceptively flat and smooth (see...
Figure S1). Hence, although checking that testing whether bulk density and soil carbon content measurements follows indeed this kind follow this type of relationship provides a good indicator of the dataset quality, it is not recommended to infer soil carbon profiles from these empirical relationships.

5 Loisel et al. (2014) choose an arbitrary cutoff value of 0.5 g.cm$^{-3}$ to distinguish peat and non-peat material. It also roughly corresponds to the separation separation between samples with mass carbon content exceeding 15% and the others (Figures 9.a,b,c). Below this threshold (i.e. for fully organic samples), there is was a linear relationship between bulk density $\rho_{\text{bulk}}$ and soil carbon density $\rho_{C}$ (Figures 9.b), indicating a rather homogeneous soil carbon content $f_{C}$ for organic samples. For mixed-material and mineral samples, such relationship is not true.

10 The well-known high water-retention capacity of peat soils (e.g. (Boelter, 1969)) is also observed in was also observed here (Figure 9.c) as the higher values of soil-water content are were found in the samples with the highest carbon content and lowest bulk densities.

15 Finally, when using these data for performing a detailed 1-dimensional evaluation of the litter and soil carbon together with the C02 and CH4 emissions simulated by a land-surface model validation, it is preferable to only best to use the soil carbon data corresponding to the automatic chambers area, that is the profiles from plots $T1 - 0$ to $T1 - 20$.

5 Code and data availability

All the data used to produce the tables and figures of the paper are freely available on the repository : https://doi.org/10.1594/PANGAEA.909899 (Morel et al., 2019b)

6 Conclusions and perspectives

In this paper, we have provided a complete description of a new dataset of the current distribution of soil organic carbon and nitrogen storage at the Nuuk peatland. This dataset is one of the very few on Greenland fens and will help in better understanding these poorly documented ecosystems. All data are in the range of previous studies (Yu et al., 2011; Yu, 2012; Loisel et al., 2014). Moreover, automatic chambers fluxes measurement the existing arctic and low arctic fen studies. All data are in the range of previous studies. Automatic chamber flux measurements and carbon sampling localisations are in the same spot, making are being recorded at the same location, making the Nuuk-fen dataset an ideal candidate for evaluating ability the accuracy of land surface models to reproduce model simulations of both soil carbon profiles and greenhouse gas emissions at the scale of the site.

30 It will allow in the near future a complete evaluation of the biogeochemical model presented in Morel et al. (2019a). Completing this evaluation could help eventually resolve issues raised by Chadburn et al. (2017). It could also be used to further
validate recent developments in carbon and/or peatlands modules for larger scale studies, such as the specific peatland module developed by Largeron et al. (2018) or the soil carbon representation specific to fen and peatlands of Qiu et al. (2018).

7 Calculation of 95% confidence interval soil profile

The sampling mean most likely follows a normal distribution. Under this hypothesis, the standard error of the mean (SEM) can be calculated as 
\[
\sigma \frac{\bar{x}(z)}{\sqrt{N(z)}}
\]
with \( N(z) \) the number of samples collected at a depth \( z \) and \( \sigma(z) \) the standard deviation over those samples. The confidence interval at 95% is defined as 
\[
I(z) = \bar{x}(z) \pm 1.96 \times \sigma \frac{\bar{x}(z)}{\sqrt{N(z)}}.
\]

Author contributions. XM, BUH, MM, CD and BD designed the field campaign. XM and BUH conducted the field work, collected and prepared the samples for analysis. PA conducted the laboratory analysis. XM, CD and BD designed the manuscript. All authors contributed to the writing.

Competing interests. The authors declare that they have no conflict of interest.

(1) $r^2 = \left( \frac{\sum_{i=1}^{n} (x_i - \bar{x})(f(x_i) - \bar{f})}{\sqrt{\sum_{i=1}^{n} (x_i - \bar{x})^2} \sqrt{\sum_{i=1}^{n} (f_i - \bar{f})^2}} \right)^2$

(2) $\text{c-rmse} = \frac{1}{n} \sqrt{\sum_{i=1}^{n} (x_i - \bar{x} - (f(x_i) - \bar{f}))^2}$

(3) $\text{mae} = \frac{1}{n} \sum_{i=1}^{n} |x_i - f(x_i)|$

(4) $\text{bias} = \frac{1}{n} \sum_{i=1}^{n} (x_i - f(x_i))$
Figure 1. Left-top panel: satellite image (Google Earth© - 2009) of Kobbefjord, centered on the point 64°7’15.5”N; 51°23’10.5”W. The black rectangle represents the studied zone. Right-top panel: high-resolution photography (taken by a drone in 2015) of the studied zone floor. The white rectangle represents surrounds the fen. Bottom-panel: zoom of the fen, with the two studied transects: T1 (black circles) and T2 (blue circles). Zones highlighted in red represent the location of the automatic chambers; in green, the soil temperature probes; in yellow, the eddy flux tower.
Figure 2. Soil surface photographs along the first transect at several plots. (a) : T1-10 ; (b) : T1-30 ; (c) : T1-35 ; (d) : T1-40.
Figure 3. Topographical measurements of soil surface (red) and manual measurements of water level (blue) and organic-mineral interface (black) along both transects. Manual measurements of water level were made in July, 27\textsuperscript{th} 2017.
Figure 4. First transect soil samples after 48 hours of oven drying at 80 °C. Different samples depths are shown for plots (a) : T1 – 10 ; (b) : T1 – 25.
Figure 5. Distribution histograms ($n_{samples} = 135$) of (a) soil sample density $\rho_{sample}$ (g.cm$^{-3}$); (b) soil bulk density $\rho_{bulk}$ (g.cm$^{-3}$); (c) soil water content (%); (d) C/N Ratio (-); (e) soil carbon content $f_C$ (%); (f) soil carbon density $\rho_C$ (kgC.m$^{-3}$); (g) soil nitrogen content $f_N$ (%); (h) soil nitrogen density $\rho_N$ (kgN.m$^{-3}$). Red lines represent mean values, blue lines median values, dashed green lines upper and lower deciles.
Figure 6. Soil profiles of (a) soil bulk density $\rho_{\text{bulk}}^{\text{obs}}$ (g.cm$^{-3}$); (b) soil water content (%); (c) soil carbon content $f_C$ (%); (d) soil nitrogen content $f_N$ (%); (e) soil carbon density $\rho_C$ (kgC.m$^{-3}$); (f) soil nitrogen density $\rho_N$ (kgN.m$^{-3}$) along both transects. Dashed black line represents the measured organic-mineral interface. Grey zones indicates the absence of data (mineral soil).
Figure 7. Mean soil profiles over both transects ($n_{samples} = 135$; $n_{profiles} = 17$) of (a) soil sample density $\rho_{sample}$ (g.cm$^{-3}$); (b) soil bulk density $\rho_{bulk}$ (g.cm$^{-3}$); (c) soil water content (%); (d) C/N Ratio (-); (e) soil carbon content $f_C$ (%); (f) soil carbon density $\rho_C$ (kgC.m$^{-3}$); (g) soil nitrogen content $f_N$ (%); (h) soil nitrogen density $\rho_N$ (kgN.m$^{-3}$). Shaded area represents the 95% confidence interval.
Figure 8. Same than figure 7, except profiles depth are re-normalized from organic-mineral interface. Grey area represents the zone below the OMI.
Figure 9. Scatter plots of soil bulk density $\rho_{bulk}^{obs}$ versus (a) soil carbon content $f_C$ (%) ; (b) soil carbon density $\rho_C$ (kgC.m$^{-3}$) ; (c) soil water content (%) for the 135 samples. Red circles represents samples with carbon content exceeding 15 %, blue crosses less than 15 %.
