Tunability and Sensing Properties of Plasmonic/1D Photonic Crystal

Mohamed Shaban, Ashour M. Ahmed, Ehab Abdel-Rahman & Hany Hamdy

Gold/one-dimensional photonic crystal (Au/1D-PC) is fabricated and applied for sensitive sensing of glucose and different chemical molecules of various refractive indices. The Au layer thickness is optimized to produce surface plasmon resonance (SPR) at the right edge of the photonic band gap (PBG). As the Au deposition time increased to 60 sec, the PBG width is increased from 46 to 86 nm in correlation with the behavior of the SPR. The selectivity of the optimized Au/1D-PC sensor is tested upon the increase of the environmental refractive index of the detected molecules. The resonance wavelength and the PBG edges increased linearly and the transmitted intensity increased nonlinearly as the environment refractive index increased. The SPR splits to two modes during the detection of chloroform molecules based on the localized capacitive coupling of Au particles. Also, this structure shows high sensitivity at different glucose concentrations. The PBG and SPR are shifted to longer wavelengths, and PBG width is decreased linearly with a rate of 16.04 Å/μg/mm³ as the glucose concentration increased. The proposed structure merits; operation at room temperature, compact size, and easy fabrication; suggest that the proposed structure can be efficiently used for the biomedical and chemical application.

In past years, photonic crystals (PCs) are receiving increasing attention in both industry and academia due to their applications in photonics, electronics and biochemical. The PCs are a relatively new class of materials in which the refractive index is periodic in one-dimension (1D- PC), two-dimension (2D- PC), and three-dimension (3D-PC)\(^1\). The length scale of spatial periodicity is on the order of the wavelength of light propagating in the structure. When light waves incident on the PC, some photons are allowed to propagate through the PC and others are forbidden (totally reflected)\(^1\). The forbidden photon in particular frequency ranges leads to the appearance of stop bands in the transmission spectra. This usually referred to as photonic band gaps (PBGs), in analogy to the electronic band gaps of semiconductors\(^4\). Therefore, the PCs can be used to control light with fantastic facility and construct integrated optical devices that are impossible with conventional optics\(^5\). 1D-PCs are studied more attractive than 2D-PCs and 3D-PCs because of its simple fabrication and low cost\(^6,7\). For the 1D-PC synthesis, different methods such as plasma enhanced chemical vapor deposition (PECVD), radio frequency (RF) magnetron sputtering, spray pyrolysis deposition, thermal evaporation and some other has already been demonstrated. The PECVD offers several potential advantages over current processing technologies. Foremost is the opportunity to reduce deposition temperatures to below 400 °C\(^8,9\). Second, reactant species may be introduced into the low-pressure PECVD reactor by direct liquid injection. Third, it is more suitable for production high-quality thin films with excellent adhesion and controlling the layers thickness.

By monitoring PBG change or shift, photonic crystals have been used as optical sensors in many different areas such as environmental monitoring, chemical, and biological detections\(^10\). PCs sensors show high sensitivity, small size, and a wide dynamic range. Also, they are practical for on-chip integration with the incorporation of light sources and detectors\(^11\). Today, the refractive index (RI) is one of the most important optical parameters for the materials because it offers an indication of several physical and chemical changes. Hence, RI detection method is very important in industrially, environmentally, clinically, and to food processing monitoring\(^12,13\). In other side, quantitative detection of the glucose concentration (GC) has attracted much attention due to its significant index in clinical diagnoses, regulation of metabolism, and biochemical analysis\(^14,15\). For all of that, the development of simple, fast, cheap and high-performance sensors for the environment RI and GC has been the subject of concern for decades.

Since the first application of the surface plasmon resonance (SPR) phenomenon for sensing almost 30 years ago, this method has made significant advances in instrumentation development and applications. Recently, SPR combined with PCs for active sensing of environmental RI change. Biswas et al. designed a new family of hollow-core photonic crystal fibers with embedded metal wires for sensitive refractive index measurement of fluids. Otupiri et al. used numerical analysis to present a novel birefringent photonic crystal fiber biosensor constructed on the SPR model for sensing more than one analyte. Zhao et al. reviewed the research developments of the photonic crystal fiber based surface plasmon resonance (PCF-SPR) chemical sensors. Lately, Gao et al. presented a mode expansion method that can quantitatively describe guided resonances and bound states in the continuum (BICs) in periodic 1D-PC slabs, which is very promising for sensing applications.

However, very limited attempts have been made to combine 1D-PC with the SPR to improve the sensing properties. Baryshev and Merzlikin showed theoretically that a plasmonic 1D PC-based optical sensors exhibited good robustness and enhanced sensitivity in comparison with the conventional surface plasmon and Bloch surface wave sensors. Lee et al. showed theoretically enhanced nonlinear optical effects due to the excitation of optical Tamm plasmon polaritons in 1D-PC structures. Recently, Auguié et al. investigated with comprehensive numerical simulations the conditions for optimized coupling between light and Tamm plasmons excited at normal incidence from either side of the Au- distributed Bragg reflectors (DBR) structure. So the optimized design of plasmonic 1D-PC opens up the possibility to increase the sensitivity of the PC. In addition, a nanometer plasmonic layer such as Au layer will be serving as protection layer due to the Au has high resistance to oxidation and corrosion in various environmental conditions and hence improving the stability of the PC sensor. Here, a simple 1D-PC terminated with Au nanostructured thin film is fabricated, characterized and used as an optical sensor for different chemical and biological molecules. Effect of the Au thickness and principles of optical sensing are discussed.

Results and Discussion

Characterization of the Au/1D-PC. Figure 1(a) shows a cross-sectional SEM image of a ten-layer 1D-PC made of SiO2/SiN deposited alternately on the glass substrate and terminated with Au layer. Multilayered stacks are clearly observed in this figure. The dark layers are the low refractive index layers (SiO2), and the white layers are the high refractive index layers (SiN). As seen in this figure, the thicknesses of SiO2, SiN, and Au layers are uniform and ~98, 112 and 126 nm, respectively.

Figure 1(b) shows top-view SEM images of the deposited Au layer at two different magnifications. As seen from these images, a uniform nanostructured Au layer covers the top surface of the 1D-PC. The PC surface is well covered with Au grains that are almost uniformly distributed over the surface. These grains are grown by the agglomeration of almost uniformly distributed spherical Au nanoparticles. These Au nanoparticles show a narrow size distribution and a very high density per unit area. The diameters of the nanoparticles are varied from 10.03 nm to 27.40 nm with an average of 18.34 nm.

The 3D and 2D AFM images of Au layer are shown in Fig. 2. The surface of the Au/1D-PC possesses peak and valley regions and are not absolutely flat surfaces. The bright areas show the overgrown Au crystallites of well-developed grain morphology. The Surface roughness is characterized by calculating the roughness parameters which are estimated by analyzing the topography scans of the sample's surface. The roughness parameters include root mean square roughness (Rms = 7.30 nm ), average roughness (Rav = 5.58 nm), maximum peak height (Rp = 15.01 nm), maximum valley depth (Rv = 9.96 nm), and difference between Rp and Rv (Rv<sub>r</sub> = 24.97 nm). Then, the proposed Au/1D-PC possesses good morphology and huge surface area with high density plasmonic hot spots. Then, the proposed structure may be used in different applications including sensors, catalysts, and optoelectronic components.

Qualitative and quantitative chemical composition of the fabricated 1D-PC coated with Au for 60 sec was studied using EDX. The EDX spectrum in Fig. 3 clearly confirms the presence of O, Si, Au, and N peaks. The
quantitative results were 42.13% O, 34.71% Si, 19.38% Au, and 3.78% N, which indicates the high purity of the fabricated structures. No traces are detected from the glass substrate.

From optical transmission of uncoated (SiO$_2$/SiN)$_{10}$ PC (black square and solid line) in Fig. 4(a), it can be seen that there is a PBG (i.e., a region of nearly zero transmittance). The left and right band edges of this PC are at $\lambda_L = 615$ nm and $\lambda_R = 660$ nm. The width of PBG is small, $\Delta \lambda_{\text{PBG}} = \lambda_R - \lambda_L = 45$ nm because the PBG width is directly proportional to the refractive index contrast, $\Delta n$, between the two layers (SiN and SiO$_2$). The formation of PBG can be explained by the interference of light, which is reflected by the periodic index variations. According to the optics theory, the light beam incident on the PC will be partly transmitted and partly reflected at each interface between SiN and SiO$_2$. There are multiple reflections arise from the periodic variation of the refractive index of the PC. Then, the reflected waves produce multiple destructive or constructive interferences. The very high reflectivity (very low transmission) of light over a certain range of wavelengths is caused by constructive interference of the in-phase beams and called photonic band gap (PBG). Also, there are many ripples in the transmission response outside the PBG.

The optical response of the PC was observed to be markedly affected by the Au coating. There is a new minimum appear in the transmission spectrum of Au-PC around 723 nm at the right edge of the PBG as illustrated in Fig. 4(a and b). The same minimum was observed at 720 nm in the transmission spectrum of a glass slide coated with Au due to the SPR of Au layer, Fig. 4(d). The surface plasmon is a transverse-magnetic (TM) waves propagate at the metal-dielectric interface with electric field decaying exponentially in both media. The surface plasmon wave (SPW) is excited when the free electrons in the conduction band of noble metal are induced to coherent oscillation by interacting electromagnetic fields of incident light at resonance, the energy of the incident photon is transferred for the excitation of the SPR, resulting in a sharp dip in the transmittance spectrum at a particular wavelength. The curved surface of the Au nanoparticle creates a sufficient restoring force on the conduction electrons. Therefore, the SPR is characterized by substantial enhancements of the local electric fields surrounding the Au nanoparticles. The increasing in the local electric field intensity at the surrounding medium/Au and Au/PC interfaces will enhance the interaction between light and PC, and thus improves performance parameters of the PC as an optical sensor. The position of SPRs was shifted to longer wavelengths as the Au-deposition time increased, Fig. 4(c). This red shift may be ascribed to the size effect. As the size increased, the charge separation between the positive ion and the surface electron is increased. This leads to a decrease of the Coulombic restoring effect.
force which acting on the oscillating electrons. As a result, the energy of the plasmon resonance is reduced, and
the peak of the plasmon resonance is red-shifted. Also, the transmittance of PC is decaying with increasing the
thickness of Au film. This result from the dielectric constant of a noble metal such as Au is a complex with a rel-
atively large imaginary part. The light absorption is increased as the thickness of Au layer increased. The absorp-
tion of noble metals is due to the electrons jumps between occupied bound d states and un-occupied hybridized
sp states above the Fermi level in the visible range33.

With increasing Au thickness, the left band edge, \( \lambda_L \), is shifted to the shorter wavelength while the right
band edges, \( \lambda_R \), is shifted to the longer wavelength and that causes an increase in the PBGs width as shown in
Fig. 4(e and f). This is ascribed to the increase of the effective optical thickness of the structure after the Au depo-
sition, which is the product of the thickness and the refractive index of the PC structure, according to the optical
Bragg equation. According to the linear fitting of the experimental data, solid lines in Fig. 4(e), the shifts of \( \lambda_L \) and
\( \lambda_R \) are given by the empirical equations;

\[
\begin{align*}
\lambda_L (\text{nm}) &= 611.95 - 0.305 t_{\text{D-Au}} (R^2 = 0.91522) \\
\lambda_R (\text{nm}) &= 662.59 + 0.316 t_{\text{D-Au}} (R^2 = 0.92183)
\end{align*}
\]

(1)

where \( t_{\text{D-Au}} \) the deposition time of Au in second and \( R^2 \) is the coefficient of determination or the square of the
correlation coefficient between the linear fitting and the experimental data at the right and left edges of the PBG.
As shown the rate of shift of \( \lambda_R \) is greater than the rate of shift of \( \lambda_L \). This means that the existence of the SPR plays
an important role in the tunability of the PBG width. Figure 4(f) clearly indicates a nonlinear increase of the PBG
width and the best fitting for the experimental data is the exponential equation as shown in the figure.
Refractive index sensing application. After fabrication and characterization of Au/PC, its performance as an optical sensor device for RI and GC was tested by immersing the PC into a series of solutions. Figure 5(a) shows the transmission spectra of Au/PC loaded with methanol, water, isopropanol, 2-methoxyethanol, and chloroform with RI of 1.3284, 1.333, 1.3772, 1.4021 and 1.4458, respectively. The PBG is red-shifted as the environmental RI increased. This ascribed to the decrease of the RI contrast as the environmental RI increased; hence both \( \lambda_R \) and \( \lambda_L \) are moving toward the longer wavelengths. Also, the transmittance of the PC increases with increasing the environmental RI. This is in agreement with previously reported results. With increasing the environmental RI, the Fresnel reflection \( R = \frac{\eta_{PC} - \eta_{env}}{\eta_{PC} + \eta_{env}} \), at the PC/Au/environment interfaces decreases and hence the transmitted intensity increases as the environmental RI increased from 1.000 to 1.4458.

Figure 5(b,c) shows the SPR wavelength and transmission intensity as a function of RI of surrounding medium. The SPRs are linearly shifted to longer wavelengths, and SPR transmission is exponentially increased as the refractive index of the environmental solution increased. This may be ascribed to two reasons. (1) The polarization of the adsorbed molecules of liquid due to the presence of electric field around the Au nanoparticle surface. This polarized medium compensates for some of the charges on the nanoparticle surface and can act as a bridge between the nanoparticles of Au layer to produce strong overlapping of Au local electric field. (2) The increasing of the refractive index for the environmental solution reduces the Coulombic restoring force that acting on the oscillation electrons in the Au particle. This reduction leads to a red shift in the plasmonic peak. The linearity of the relationship between changes in guided resonance spectral location and surrounding RI indicates the symmetry of the fabricated sensor. The obtained empirical formula is
Also, there is a new minimum in the optical transmission is appear at 744.5 nm when the Au/PC loaded with chloroform of high RI (n = 1.4458) as indicated by rows in Fig. 5(b). The SPW strongly depends on the interaction of the molecules of sensing medium and Au nanoparticles. The chloroform has high adhesion so that when it comes in contact with the Au-PC surface, the molecules of chloroform get better adsorbed on Au surface. The hard binding of these molecules with the Au layer can enhance the inter-coupling between the Au nanoparticles. Then, the local electric field intensity around the Au particles is increased. Also, the presence of electric field around the Au nanoparticle surface also induces the polarization of the adsorbed chloroform molecules. A higher value of refractive index of chloroform results in more polarized charges for chloroform molecules. Hence, the polarized chloroform molecules can be acting as a bridge between the nanoparticles of Au layer. This produces strong overlapping of Au local electric field with the molecules of chloroform. Therefore, there is a redistribution of surface charges on adjacent Au nanoparticles which results in the splitting of SPR to two modes and the higher order SPR (new plasmon mode in the spectrum) can be achieved based on the localized capacitive coupling of Au particles. In this case, the separation between the SPR modes, Fig. 5(b), is Δλ = 21.5 nm.

Figure 5(d and e) show the variation of the position and transmission of left and right edge of PBG with the environmental RI. As the RI increased, the values of λ_L and λ_R are shifted toward longer wavelengths. The shifts can be linearly fitted according to the equations:

$$\lambda_{L} = 46.73 \, n + 532.04 \quad (R^2 = 0.9833)$$

$$\lambda_{R} = 56.14 \, n + 640.41 \quad (R^2 = 0.9774)$$

The performance of the PC as RI sensors is evaluated using the sensitivity parameter (S_n) and signal-to-noise ratio (SNR). The sensitivity is given by

$$S_n = \frac{\Delta \lambda_{res}}{\Delta n}$$

where Δλ_res is the resonance wavelength shift and Δn is the change in the environmental refractive index. The refractive index and resonance wavelength of air were used as references to calculate Δλ_res and Δn for the different liquid materials, i.e, Δλ_res = λ_res(liquid) − λ_res(air) and Δn = n(liquid) − n(air).

Besides the sensitivity, signal-to-noise ratio (SNR), detection limit (δn), sensor resolution (SR), and figure of merits (FOM) are also important parameters to evaluate sensor performance. These parameters can be found using the following expressions:

$$SNR = \frac{\Delta \lambda_{res}}{\Delta \lambda_{1/2}}$$

$$\delta n = \frac{1}{S} \frac{\Delta \lambda_{1/2}}{1.5 \, (SNR)^{0.25}}$$

$$SR = \delta n S$$

$$FOM = \frac{S}{\Delta \lambda_{1/2}}$$

where Δλ_{1/2} is the full width at half maximum of the transmission dip.

Using Fig. 5 and Equations (4)–(8), S_n, SNR, δn, SR, and FOM are calculated at the peak of surface plasmon resonance and shown in Table 1. From this Table, the average sensitivity is 50.23 nm/RIU. According to the linear fitting of the experimental data, the values of sensitivity, slope of the straight line, at λ(res), λ_L and λ_R are 48.56, 46.73 and 56.14 nm/RIU, respectively. The observed trend is that longer wavelength guided resonances will have a higher sensitivity. This indicates 20% increase in the sensitivity of right PBG edge relative to that of left PBG. This may be attributed to the existence of the SPR very close to the right PBG edge which increases the spectral sensitivity and quality factors of right edge peak resulting in substantial enhancement of refractive index sensitivity. These sensitivities are better than that previously reported for photonic crystal fiber tip interferometer.

| n_r | Δn_r (RIU) | λ_res (nm) | Δλ_res (nm) | Δλ_{1/2} (nm) | Δλ_res/Δλ_{1/2} (nm) | SNR = Δλ_res/Δλ_{1/2} (nm/RIU) | δn | FOM | SR |
|-----|------------|------------|-------------|---------------|-----------------------|---------------------------------|-----|-----|-----|

Table 1. Sensitivity parameter, S_n, SNR, δn, SR, and FOM values for Au/1D PC sensor obtained for different environmental refractive indices.
(11.5 nm/RIU over the RI range of 1.33–1.40)\textsuperscript{12}, microfiber device (30.49 nm/RIU over the RI range of 1.334–1.348)\textsuperscript{40}, Mach-Zehnder interferometer (15–40 nm/RIU)\textsuperscript{41–43}, multilayer coated microsphere (maximum, 12.16 nm/RIU)\textsuperscript{44}, and fiber grating sensor (below 5 nm/RIU)\textsuperscript{45}. However, theoretical studies using finite different time domain (FDTD), COMSOL showed higher sensitivity than that shown here for more complicated proposed structures. These include photonic crystal waveguide-based sensors described by Bagci and Akaoglu (max Sn = 282.4 nm/RIU)\textsuperscript{11}, sensors based on SPR in plastic optical fiber by Cennamo et al. (549 nm/RIU and 1325 nm/RIU)\textsuperscript{46}, 2D photonic crystal slab biosensors by El-Beheiry et al. (max Sn = 902 nm/RIU for TM-like conditions)\textsuperscript{38}, SPR-based optical fiber sensor by Al-Qazwini et al. (max Sn = 20310 nm/RIU)\textsuperscript{47}, and multi-core flat fiber based surface plasmon resonance (MCFF SPR) by Rifat et al. (max Sn = 23000 nm/RIU)\textsuperscript{48}.

Detection of glucose concentration application. The PC tested as an optical sensor device for glucose by immersing it into a series of aqueous GC solutions of different concentrations. Transmission spectra of PC immersed into glucose solutions with concentrations 0–0.163 g/dl are shown in Fig. 6(a and b). The spectral analyses of the transmission spectra are shown in Fig. 6(c–e) for the surface plasmon resonance (λ_{SPR}), the left edge (λ_{L}), and right edge (λ_{R}) of the PBG. These figures clearly show a nonlinear shift of the guided wavelengths to longer wavelengths as the GCs increased. Also, the PBG is shifted toward higher wavelengths accompanied with an increase in the transmitted intensity at lower GCs and tiny increase or saturation at higher GCs as observed in Fig. 6. This behavior well correlates with the change of the RI contrast between the Au/PC and the environmental glucose layer.

Figure 6. (a,b) Transmission spectra of Au-PC in response to the introduction of glucose solutions of different concentrations in the microfluidic channel (0.00, 0.005, 0.031 and 0.163 g/dl), (c) the guided wavelength and transmission intensity of SPR mode, (d) left edge, and (e) right edge of the PBG as function of GCs; and (f) variation of PBG width with the GCs.
The presented plasmonic 1D-PC is suitable as an optical sensor for RI and GC. The significant advantages of the presented sensor; compact size, low fabrication cost, better performance regarding sensitivity and resolution, and large scale fabrication availability; suggest the use of this sensor for the biochemical and biomedical application.

**Conclusions**

Here, we have successfully designed an optical sensor based on 1D-PC terminated with plasmonic nanolayer by PECVD and sputter coating techniques. The fabricated sensor was efficiently applied for the detection of glucose of different concentrations and different chemical molecules of various refractive indices. The thickness of the Au nanolayer was successfully optimized to produce surface plasmon resonance (SPR) at the right edge of the photonic band gap (PBG) and to improve the sensitivity and stability of the proposed sensor. The morphology and chemical composition of the fabricated multilayered structure, Au/SiO2/SiN 1D-PC, was investigated. This sensor shows higher sensitivity ~50.23 nm/RIU and lower signal-to-noise ratio ~0.46 compared to previously reported experimental values for more complicated 1D-PC. 20% increase in the sensitivity of right PBG edge relative to that of left PBG edge was observed and ascribed to the existence of SPR very close to the right edge. The symmetry of the fabricated structure as RI sensor was confirmed by the linearity of the relationship between changes in guided resonance spectral location (λ_{SPR}, λ_{L} and λ_{R}) and surrounding RI indicates. A new minimum in the optical transmission appears at 744.5 nm when the Au/PC loaded with chloroform of high RI (n = 1.4458) due to the splitting of SPR. Also, during the detection of glucose concentrations (GC), the PBG width decreased linearly with rate 16.04 Å/(μl) with different refractive indices. A schematic diagram of the experimental set-up (sample detection setup) is presented in the Supporting data; Fig. S1. The liquids were methanol, water, isopropanol, and distance 8 cm in front of the Au target (99.99%) for different lengths of time (from 10 to 60 sec). The deposition rate of the Au layer on the 1D-PC is 2.1 nm/sec. For comparison, glass substrates were coated with the same Au layers, under the same conditions, to understand the effect of Au and its SPR on the optical properties of 1D-PC.

**Methods**

**Sensor fabrication.** SiN layer was deposited using a PECVD system (PlasmaPro 100 Stratum, Oxford Instruments) with a gaseous mixture of high-purity (99.99%) SiH₄/NH₃/N₂. The glass substrate has been heated to 200 °C during the deposition. To minimize the plasma damage of the film surface during the deposition, a high excitation frequency of 13.56 MHz was applied. 4.5% SiH₄/95.5% N₂ mixture was used as process gases. The NH₃ flow was fixed at 50 sccm, the pressure at 200 mTorr and the plasma power at 100 W during this experiment. For the second layer, SiO₂ layer was formed by PECVD at 200 °C using SiH₄/N₂O gas at 100 W- RF power, making a film thickness of 100 nm using the same frequency.

Au layers of different thicknesses were deposited on the top surface of 1D-PC by DC sputtering at pressure 2 Torr and distance 8 cm in front of the Au target (99.99%) for different lengths of time (from 10 to 60 sec). The deposition rate of the Au layer on the 1D-PC is 2.1 nm/sec. For comparison, glass substrates were coated with the same Au layers, under the same conditions, to understand the effect of Au and its SPR on the optical properties of 1D-PC.

**Sensor Characterization.** The morphological features of the 1D-PC were measured by using both field emission-scanning electron microscope (FE-SEM, ZEISS SUPRA 55 VP and ZEISS LEO, Gemini Column) and atomic force microscope (AFM, PARK SYSTEM, XE-100E). The chemical composition was studied using energy dispersive X-ray spectrometer (EDX; Oxford Link ISIS 300 EDX). Optical spectra in the spectral range from 300 to 1000 nm were measured with increment 1 nm using UV/VIS/NIR 3700 double beam Shimadzu spectrophotometer. All optical measurements in this research were conducted at the normal incident and room temperature.

**Sensing properties measurements.** The sensing properties of the fabricated sensor were investigated by measuring transmission spectra of the Au/(SiN/SiO₂)30/glass after loading the sample with small amounts of liquids (<0.1 μl) with different refractive indices. A schematic diagram of the experimental set-up (sample detection setup) is presented in the Supporting data; Fig. S1. The liquids were methanol, water, isopropanol,
2-methoxyethanol and chloroform with RI of the immersion liquid varying between 1.328 and 1.4458. This RI range is very necessary for biomedical and chemical sensor application. Also, examine the optical response of the sensor to glucose solutions of different concentrations ranging from 0.009 to 0.163 g/dl. The glucose solution was prepared in DI water and sonicated to get a homogeneous mixture.

**Author Contributions**

M. Shaban and A.M. Ahmed designed the experiments, characterized the samples, and contributed to the writing of the manuscript. E. Abdel-Rahman and H. Hamdy analyzed the data.
