Interaction between the basolateral amygdala and dorsal hippocampus is critical for cocaine memory consolidation and subsequent drug context-induced cocaine-seeking behavior in rats

Contextual stimulus control over instrumental drug-seeking behavior relies on the consolidation of context-response-drug associative memories into long-term memory storage following retrieval-induced destabilization. According to previous studies, the basolateral amygdala (BLA) and dorsal hippocampus (DH) regulate cocaine-associated memory consolidation; however, it is not known whether these brain regions interact or independently control this phenomenon. To investigate this question, rats were trained to lever press for cocaine reinforcement in a different environmental context followed by extinction training in a different context. Rats were then briefly re-exposed to the cocaine-paired context to destabilize cocaine-related memories, or they were exposed to an unpaired context. Immediately thereafter, the rats received unilateral microinfusions of anisomycin (ANI) into the BLA plus baclofen/muscimol (B/M) into the contralateral (BLA/DH disconnection) or ipsilateral DH, or they received contralateral or ipsilateral microinfusions of vehicle. They then remained in their home cages overnight or for 21 d, followed by additional extinction training and a test of cocaine-seeking behavior (nonreinforced active lever responding). BLA/DH disconnection following re-exposure to the cocaine-paired context, but not the unpaired context, impaired subsequent drug context-induced cocaine-seeking behavior relative to vehicle or ipsilateral ANI + B/M treatment. Prolonged home cage stay elicited a time-dependent increase, or incubation, of drug-context-induced cocaine-seeking behavior, and BLA/DH disconnection inhibited this incubation effect despite some recovery of cocaine-seeking behavior. Thus, the BLA and DH interact to regulate the consolidation of cocaine-related associative memories, thereby facilitating the ability of drug-paired contexts to trigger cocaine-seeking behavior and contributing to the incubation of cocaine-seeking behavior.

[Supplemental material is available for this article.]

Exposure to cocaine-associated environments can elicit craving and promote relapse in former addicts (Childress et al. 1988; O’Brien et al. 1992; Foltin and Haney 2000). Similarly, re-exposure to a previously cocaine-paired context reinstates extinguished cocaine-seeking behavior in rats, and this phenomenon depends on robust context-response-cocaine associations (Jalal et al. 2001; Fuchs et al. 2005; Kears and Weiss 2007; Crombag et al. 2008). According to the memory consolidation hypothesis, the memories of previously learned associations are rendered labile during retrieval and must be restabilized, or “reconsolidated,” into long-term memory storage in order to exert persistent stimulus control over conditioned behaviors (Misanin et al. 1968; Lewis 1979; Nader et al. 2000a; Tronson and Taylor 2007), including drug-seeking behavior (Lee et al. 2005; Miller and Marshall 2005; Bernardi et al. 2006, 2009; Milekic et al. 2006; Valjent et al. 2006; Diergaarde et al. 2008). Hence, a greater understanding of the neural circuitry and mechanisms underlying cocaine-related memory consolidation may inform the development of novel treatments for drug addiction (Taylor et al. 2009; Milton and Everitt 2010).

The basolateral amygdala (BLA) is integral to the expression of both cue- and context-induced reinstatement of cocaine seeking (Meil and See 1997; Fuchs et al. 2002, 2005, 2007; Kantak et al. 2002) and is a site for memory consolidation (Nader et al. 2000a; Milekic et al. 2007; Mamiya et al. 2009; Li et al. 2010). The BLA is critically involved in the consolidation of conditioned stimulus (CS)-drug associative memories that regulate drug-conditioned place preference (Milekic et al. 2006; Li et al. 2010; Théberge et al. 2010), conditioned reinforcement, and drug-seeking behavior (Lee et al. 2005, 2006; Milton et al. 2008; Théberge et al. 2010). Furthermore, research from our laboratory has demonstrated that anisomycin (ANI)-sensitive processes (i.e., protein synthesis and/or post-translational modification) for review, see Gold 2008) in the BLA control the consolidation of context-response-cocaine associative memories and the subsequent ability of a drug-paired context to reinstate extinguished cocaine-seeking behavior (Fuchs et al. 2009).

Similar to the BLA, the dorsal hippocampus (DH) is required for the expression of drug context-induced cocaine-seeking behavior in rats (Fuchs et al. 2005, 2007), but its exact contribution to the consolidation of cocaine-related associative memories remains unclear. Tetrodotoxin-induced neuronal inactivation of, but not ANI treatment in, the DH following re-exposure to a cocaine-paired context inhibits subsequent...
drug context-induced reinstatement of cocaine-seeking behavior (Ramirez et al. 2009). This effect is cocaine memory reactivation-dependent, indicating that, while the DH is not a critical site for protein synthesis and/or post-translational modification required for memory re-stabilization, per se, it is necessary for the utilization of memories that have been reconsolidated elsewhere, perhaps in the BLA.

Intrahemispheric interaction between the BLA and DH is required for the expression of drug context-induced cocaine-seeking behavior (Fuchs et al. 2007). Thus, interactions between these brain regions may also be necessary for memory reconsolidation, including the stabilization of cocaine-related associative memories that regulate cocaine-seeking behavior. In support of this idea, neuronal populations within subregions of the BLA and DH exhibit synchronized neural activity concomitant with the reconsolidation of remote fear memories (Narayan et al. 2007). However, to date, it has not been investigated whether the BLA and DH interact or independently regulate memory reconsolidation. Hence, Experiment 1 in the present study employed a disconnection manipulation to test the hypothesis that intrahemispheric interaction between the BLA and DH at the time of memory reconsolidation is necessary for the ability of a cocaine-paired context to subsequently elicit cocaine-seeking behavior. Additional experiments examined whether the effects of BLA/DH functional disconnection at the time of memory restabilization were memory reactivation-dependent (Experiment 2) and whether BLA/DH functional disconnection produced prolonged impairment in drug context-induced cocaine-seeking behavior (Experiment 3), as is expected following genuine memory reconsolidation impairment (Alberini et al. 2006; Nader and Wang 2006).

Results

Histology
Schematics and photomicrographs representing cannula placements are included in Figure 1. The target brain regions were defined as the lateral and basolateral nuclei of the amygdala and the dorsal hippocampus proper. Further inspection of neural tissue using high power microscopy revealed no indication of tissue damage (i.e., extensive cell loss or gliosis). Data from rats with misplaced cannulae were excluded from subsequent statistical analyses. The resulting n’s per vehicle (VEH)- and drug-treated groups were: contralateral VEH (BLA) + VEH (DH) 0 d, n = 8; contralateral VEH (BLA) + VEH (DH) 21 d, n = 7; contralateral ANI (BLA) + B/M (DH) 0 d, n = 10; contralateral ANI (BLA) + B/M (DH) 21 d, n = 7; ipsilateral VEH (BLA) + VEH (DH), n = 8; ipsilateral ANI (BLA) + B/M (DH), n = 7; no reactivation contralateral VEH (BLA) + VEH (DH), n = 7; and no reactivation contralateral ANI (BLA) + B/M (DH), n = 7.

Behavioral history
Analysis of variance (ANOVA) did not indicate any pre-existing differences between the groups in cocaine intake, in active or inactive lever responding during cocaine self-administration training, extinction training, during the memory reactivation session, or in the number of days required to reach the extinction criterion before testing. These data are provided in Supplementary Table S1. Correlational analyses revealed that active lever responding during the memory reactivation session did not significantly predict active lever responding during the test of drug context-induced cocaine-seeking behavior (Ramirez et al. 2009).

Figure 1. Schematics and photomicrographs depicting cannula placement. Arrows mark the most ventral point of injector cannula tracts for cannulae aimed at the BLA and DH on photomicrographs of representative cresyl violet-stained sections. The symbols on the schematics denote the most ventral point of the injector cannula tracts for rats that received unilateral microinfusions of vehicle into the BLA plus vehicle into the contralateral DH (open circles), anisomycin (ANI) into the BLA plus baclofen/muscimol (B/M) into the contralateral DH (filled-in, black circles). VEH into the BLA plus vehicle into the ipsilateral DH (open triangles), or ANI into the BLA plus B/M into the ipsilateral DH (filled-in, gray triangles). The groups were assigned to remain in their home cages overnight (i.e., 0 d) or for 21 d following the intracranial manipulations. Additionally, control groups received microinfusions following exposure to an unpaired context and remained in their home cages overnight following the intracranial manipulations. Numbers indicate the distance from bregma in mm, according to the rat brain atlas of Paxinos and Watson (1997).
context-induced cocaine seeking for the groups that had received VEH (r = 0.114, P = 0.604) or ANI + B/M treatment following the memory reactivation session (r = 0.496, P = 0.495). Furthermore, none of the analyses revealed hemisphere-dependent effects (i.e., laterality, data not shown). Only statistically significant effects are reported below. The eta-squared estimates of effect size for all statistically significant effects ranged between 0.015 and 0.770.

Experime nt 1

Experiment 1 was designed to evaluate whether intrahemispheric interaction between the BLA and DH is necessary for cocaine-related memory reconsolidation and for the subsequent ability of a cocaine-paired context to reinstate cocaine-seeking behavior (see experimental timeline in Fig. 2A). This was achieved by examining the effects of functional disconnection of the BLA and DH following cocaine memory reactivation (i.e., re-exposure to the previously cocaine-paired context) on drug context-induced cocaine-seeking behavior. Rats received unilateral infusions of ANI into the BLA plus B/M into the contralateral DH (disconnection) or ipsilateral DH (ipsilateral control). Additional control groups received ipsilateral or contralateral infusions of VEH into the BLA and DH. The contralateral ANI + B/M manipulation was expected to bilaterally disrupt putative intrahemispheric interactions between the BLA and DH. Conversely, the ipsilateral manipulation was expected to bilaterally disrupt interhemispheric connections between the BLA and DH while sparing intrahemispheric interactions between these brain regions in the unmanipulated hemisphere (Olton et al. 1982; Gaffan et al. 1993). Thus, it was postulated that requisite intrahemispheric interactions between the BLA and DH would be indicated by greater deficit in cocaine seeking following the contralateral manipulation relative to the ipsilateral manipulation.

BLA/DH disconnection following cocaine memory reactivation attenuated subsequent cocaine-seeking behavior in a context- and lever-dependent manner, while the ipsilateral ANI + B/M manipulation had no effect on responding relative to VEH (see Fig. 2B). The 2 × 2 × 2 ANOVA of active lever responses indicated a significant surgery type × treatment × context interaction effect (F(1,29) = 4.679, P = 0.039), as well as significant surgery type × context interaction (F(1,29) = 8.473, P = 0.007), treatment × surgery type interaction (F(1,29) = 5.209, P = 0.030), context main (F(1,29) = 66.482, P < 0.001), and surgery type main (F(1,29) = 8.463, P = 0.007) effects. Thus, re-exposure to the cocaine-paired context during testing elicited an increase in active lever responding in both VEH control groups and in the ipsilateral ANI + B/M-treated control group, relative to responding in the extinction context (ANOVA context simple main effect, Tukey test, P < 0.05). Conversely, the group that had received BLA/DH disconnection manipulation (i.e., contralateral ANI + B/M treatment) following cocaine memory reactivation subsequently exhibited less active lever responding in the cocaine-paired, but not the extinction context, relative to all other groups (ANOVA treatment and surgery type simple main effects, Tukey test, P < 0.05). As a result, responding in this group was not different in the cocaine-paired and extinction contexts on the test days.

Time course analysis of active lever responding revealed that the effects of contralateral ANI + B/M treatment on drug context-induced cocaine-seeking behavior were independent of time interval (see Fig. 2D). The 2 × 2 × 6 ANOVA of active lever responses across the six 20-min intervals of the test session revealed a significant surgery type × treatment interaction effect (F(1,29) = 5.196, P = 0.030), as well as time main (F(5,145) = 10.978, P < 0.001) and surgery type main (F(1,29) = 8.45, P = 0.007) effects. Active lever responding decreased during the test session (ANOVA time main effect, interval 1 > intervals 2–6, Tukey test, P < 0.05). Collapsed across time interval, there was no difference in active lever responding between the VEH control groups and the ipsilateral ANI + B/M-treated group. In contrast, the group that had received BLA/DH disconnection manipulation following cocaine memory reactivation subsequently exhibited less active lever responding relative to all other groups (ANOVA treatment and surgery type simple main effects, Tukey test, P < 0.05). The 2 × 2 × 2 ANOVA for inactive lever responses indicated that exposure to the cocaine-paired context elicited a slight increase in inactive lever responding in all groups relative to responding in the extinction context (ANOVA context main effect only, F(1,29) = 6.599, P = 0.016) (see Fig. 2C). Time course analysis of inactive lever responses during the test of drug context-induced
cocaine seeking revealed a significant treatment × time interaction effect ($F_{(5,145)} = 2.446, P = 0.037$) and a time main effect ($F_{(5,145)} = 5.625, P < 0.001$). Independent of surgery-type, VEH groups exhibited a decrease in inactive lever responding during the test session (ANOVA time simple main effects, interval 1 > intervals 2–6, Tukey test, $P < 0.05$). Furthermore, the groups that had received ipsilateral or contralateral ANI + B/M treatment following memory reactivation exhibited less inactive lever responding than VEH groups during interval 1 (ANOVA treatment simple main effect, Tukey test, $P < 0.05$).

Motor activity
The protracted effects of intracranial manipulations on general motor activity can impact instrumental cocaine-seeking behavior. To examine this possibility, general motor activity was evaluated by measuring photobeam breaks during a 2-h session in a novel Plexiglas chamber (42 × 20 × 20 cm) that was equipped with an array of eight photodetectors. The test occurred 24 h after the test of drug context-induced cocaine seeking.

General motor activity gradually declined as rats habituated to the chamber, and this effect was independent of treatment. These data are provided in Supplementary Figure S1. The $2 \times 2 \times 6$ ANOVA of photobeam breaks revealed a significant time main effect only ($F_{(5,145)} = 104.272, P < 0.001$). Collapsed across surgery type and treatment, rats generated fewer photobeam breaks during intervals 2–6 relative to the first 20-min interval of the session (Tukey test, $P < 0.05$). Importantly, neither BLA/DH disconnection nor the ipsilateral manipulation with ANI + B/M administered following memory reactivation altered subsequent general motor activity relative to VEH treatment.

Experiment 2
Memory reconsolidation deficits are expected to depend on memory reactivation (Nader et al. 2000b; Alberini et al. 2006; Tronson and Taylor 2007). Thus, we evaluated whether the effects of BLA/DH disconnection on cocaine-seeking behavior would depend on re-exposure to the cocaine-paired context immediately prior to the disconnection manipulation. To this end, “no reactivation” control groups were exposed to a novel, unpaired context prior to receiving the BLA/DH disconnection manipulation or VEH treatment (see experimental timeline in Fig. 3A).

BLA/DH disconnection in the absence of explicit cocaine memory reactivation failed to alter drug context-induced reinstatement of cocaine-seeking behavior, relative to VEH treatment (see Fig. 3B). The $2 \times 2$ ANOVA for active lever responses revealed that exposure to the cocaine-paired context produced an increase in active lever responding in the groups that received ANI + B/M or VEH treatment following exposure to the unpaired context, relative to responding in the extinction context (ANOVA context main effect only, $F_{(1,12)} = 23.169, P < 0.001$). Furthermore, there was no difference between these groups in active lever responding in the extinction or cocaine-paired context on the test days.

The $2 \times 2$ ANOVA for inactive lever responses revealed that exposure to the cocaine-paired context on the test day elicited a slight increase in inactive lever responding in both groups, relative to responding in the extinction context (see Fig. 3C), and BLA/DH disconnection following exposure to the novel context did not subsequently alter inactive lever responding in the extinction or cocaine-paired context, relative to VEH treatment (ANOVA context main effect only, $F_{(1,12)} = 9.096, P < 0.020$).

Experiment 3
Memory reconsolidation inhibitors are expected to impair the target memory trace and, therefore, to exert an enduring effect on conditioned behavior (Alberini et al. 2006; Nader and Wang 2006). Accordingly, we examined whether BLA/DH disconnection following cocaine memory reactivation would disrupt cocaine-seeking behavior after a prolonged drug-free period (i.e., 21-d vs. overnight home cage stay, each followed by a minimum of 2 d of extinction training prior to the test of drug context-induced cocaine-seeking behavior) (see experimental timeline in Fig. 4A). During the home cage stay, rats were handled regularly.

BLA/DH disconnection following cocaine memory reactivation attenuated subsequent cocaine-seeking behavior in a context-dependent manner relative to VEH treatment, and this effect was independent of home cage condition (see Fig. 4B). The $2 \times 2 \times 2$ ANOVA for active lever responses indicated significant treatment × context interaction ($F_{(1,29)} = 29.881, P < 0.001$), home cage condition main ($F_{(1,29)} = 5.631, P = 0.010$), context main ($F_{(1,29)} = 136.433, P < 0.001$), and treatment main effects ($F_{(1,29)} = 43.263, P < 0.001$). Thus, active lever responding increased following the 21-d home cage stay, consistent with the incubation phenomenon (see Fig. 4B, inset; Tran-Nguyen et al.)
treatment \times \text{home cage condition} \times \text{time interaction effect} (F_{5,140} = 4.465, P = 0.001), as well as significant treatment \times \text{time interaction} (F_{1,28} = 3.304, P = 0.008), time main effect (F_{5,140} = 19.702, P < 0.001), treatment main effect (F_{1,28} = 39.989, P < 0.001), and home cage condition main effects (F_{5,140} = 4.343, P = 0.046). Active lever responding declined over the course of the test session in the VEH groups; however, the rate of decline differed as a function of home cage condition. Specifically, the 0-d VEH group exhibited less responding during intervals 2–6 relative to interval 1 (ANOVA time simple main effects, Tukey test, \( P < 0.05 \)). Conversely, the 21-d VEH group exhibited stable responding during intervals 1–3, and active lever responding in this group decreased during intervals 4 and 6 relative to intervals 1 and 2 (ANOVA time simple main effect, Tukey test, \( P < 0.05 \)). The 0-d ANI + B/M group exhibited low levels of responding throughout the test session, and responding in this group was significantly lower than that in the respective 0-d VEH group during interval 1 (ANOVA treatment simple main effect, Tukey test, \( P < 0.05 \)). On the other hand, the 21-d ANI + B/M group demonstrated high levels of responding during interval 1 such that responding in this group was not different than responding in the respective 21-d VEH group but also did not differ from that in the 0-d VEH or 0-d ANI + B/M groups. Interestingly, however, responding in the 21-d ANI + B/M group rapidly declined such that it was significantly lower than responding in the respective 21-d VEH group during interval 2 (ANOVA treatment simple main effect, Tukey test, \( P < 0.05 \)).

The 2 \times 2 \times 2 \text{ANOVA for inactive lever responses indicated that exposure to the cocaine-paired context elicited a slight increase in overall inactive lever responding relative to responding in the extinction context (ANOVA context main effect only, \( F_{1,29} = 7.642, P = 0.010 \)) (see Fig. 4C). Neither BLA/DH disconnection nor home cage condition altered inactive lever responding in either context. The time course of inactive lever responses during the test of drug context-induced cocaine-seeking behavior revealed that inactive lever responding declined during the session, independent of treatment or home cage condition (ANOVA time main effect only, \( F_{5,140} = 9.527, P < 0.001 \), interval 1 > intervals 2–6, Tukey test, \( P < 0.05 \)) (Fig. 4E).

Discussion

Critical involvement of intrahemispheric BLA/DH interactions in the reconsolidation of cocaine-related memories that control drug context-induced cocaine-seeking behavior

To our knowledge, the present study offers the first demonstration that functional interaction between the BLA and DH is required for the reconsolidation of cocaine-related associative memories that underlie the ability of a cocaine-paired environmental context to reinitiate extinguished cocaine-seeking behavior. To test for functional interdependence between the BLA and DH, a disconnection procedure was employed. Disconnection of the BLA and DH at the putative time of memory reconsolidation was achieved by administering unilateral microinjections of ANI into the BLA and B/M into the contralateral DH following cocaine memory reactivation. This manipulation was expected to temporarily inhibit intrahemispheric interaction between the BLA and DH in both hemispheres. Conversely, the ipsilateral ANI + B/M control manipulation was expected to spare intrahemispheric information sharing between these brain regions in one hemisphere while eliminating interhemispheric interactions in both hemispheres. Importantly, ipsilateral and contralateral ANI + B/M treatment affected the same amount of neural tissue (Olton 1998; Grimm et al. 2001; Lu et al. 2004). Collapsed across home cage condition, re-exposure to the cocaine-paired context on the test day elicited increased active lever responding in the VEH groups, relative to responding in the extinction context (ANOVA context main effect, Tukey test, \( P < 0.05 \)). Furthermore, the groups that had received BLA/DH disconnection after cocaine memory reactivation subsequently exhibited less active lever responding in the cocaine-paired, but not in the extinction, context relative to the VEH groups (ANOVA treatment simple main effect, Tukey test, \( P < 0.05 \)).

Time course analysis of active lever responses during the test of drug context-induced cocaine seeking indicated that responding depended on treatment, home cage condition, and time (see Fig. 4D). The ANOVA of active lever responses during the six 20-min time intervals of the test session indicated a significant...
et al. 1982; Gaffan et al. 1993; therefore, unilateral or additive effects of the intra-BLA ANI and intra-DH B/M treatments were expected to manifest similarly following contralateral and ipsilateral administration. In the present study, BLA/DH disconnection with ANI + B/M, but not the ipsilateral manipulation with the same treatment, administered immediately after re-exposure to the cocaine-paired context, attenuated subsequent drug context-induced reinstatement of cocaine-seeking behavior relative to VEH treatment (Fig. 2B). Following cocaine memory reactivation, bilateral ANI administration into the posterior caudate putamen or bilateral tetrodotoxin-induced neural inactivation of the trunk region of the somatosensory cortex (i.e., reconsolidation inhibitor manipulations in brain regions dorsally adjacent to the BLA and DH, respectively) fails to alter later drug context-induced reinstatement (Fuchs et al. 2009; Ramirez et al. 2009).

This suggests that the intracranial manipulations in the present study were anatomically selective to the BLA and DH.

Attenuation in cocaine-seeking behavior observed 48–72 h following BLA/DH disconnection did not reflect a protracted ANI + B/M-induced motor performance deficit. In strong support of this, in Experiment 2, BLA/DH disconnection with ANI + B/M following exposure to an unpaired context did not alter subsequent cocaine-seeking behavior relative to VEH treatment (see Fig. 3B). Post-memory reactivation treatment with ANI + B/M administered into the BLA plus the contralateral or ipsilateral DH also failed to suppress general motor activity in a novel context (see Supplementary Fig. S1). Furthermore, ANI + B/M treatment failed to inhibit lever responding in the extinction context or inactive lever responding in either context (see Fig. 2B,C). These findings indicate that the attenuation in cocaine-seeking behavior produced by BLA/DH disconnection following cocaine memory reactivation was not due to ANI + B/M-induced hypoactivity or nonspecific impairment in instrumental motor behavior.

An important corollary of the memory reconsolidation hypothesis is that bona fide memory reconsolidation deficits depend on memory reactivation (Lewis 1979; Nader et al. 2000b; Sara 2000). Satisfying this requirement, BLA/DH disconnection inhibited subsequent cocaine-seeking behavior when it was induced following re-exposure to the cocaine-paired context, but not an unpaired context (i.e., in the absence of explicit cocaine-related memory reactivation) (see Fig. 3B). We have also demonstrated previously that functional disconnection of the BLA and DH at the time of reinstatement testing disrupts the expression of drug context-induced cocaine seeking (Fuchs et al. 2007). Together, these findings suggest that intrahemispheric communication between the BLA and DH critically contributes not only to the reconsolidation of reactivated cocaine-related associative memories into long-term memory storage, but also to the recall or utilization of cocaine-related associative memories in general. Thus, the BLA-DH circuitry tightly regulates the control of environmental stimuli over cocaine-seeking behavior.

While the effects of BLA/DH disconnection were specific to reactivated cocaine-related memories, implying a memory reconsolidation deficit, contralateral ANI + B/M treatment could have directly impaired the labile, post-reactivation short-term memory (PR-STM) that is to be reconsolidated. PR-STM deficits can be determined by measuring conditioned behavior during the period of putative memory lability (i.e., within 4–6 h of memory reactivation) (Nader et al. 2000a). The prolonged half-life of B/M (>24 h) (Martin and Ghez 1993, 1999) prevented such assessment of PR-STM in the present study given that BM-induced BLA/DH disconnection inhibits the expression of drug context-induced cocaine seeking behavior per se (Fuchs et al. 2007). However, somewhat mitigating the possibility that BLA/DH disconnection impaired memory reconsolidation solely by disrupting PR-STM, bilateral intra-BLA ANI treatment fails to disrupt PR-STM in the fear conditioning paradigm (Nader et al. 2000a).

In conclusion, cocaine-related memory reconsolidation likely involves interactions between the BLA and DH, similar to initial memory consolidation (for review, see Richter-Levin and Akirav 2001). Communication between the BLA and DH facilitates the consolidation of memories that guide hippocampus-dependent behaviors, including maze performance (Packard et al. 1994; Packard and Teather 1998), as well as active and passive avoidance (Roozendaal and McGaugh 1997; Rezayof et al. 2011). Specifically, the BLA appears to play a modulatory role in DH-dependent memory consolidation. Remarkably, however, BLA/DH interactions of a different nature bring about memory reconsolidation in the contextual reinstatement paradigm. The failure of post-reactivation ANI treatment in the DH to impair cocaine-seeking behavior (Ramirez et al. 2009; also see Biedenkapp and Rudy 2004) suggests that the DH is not the locus of memory re-stabilization per se, since ANI-sensitive processes are considered to be necessary for memory reconsolidation (Tronson and Taylor 2007; Nader and Einarsson 2010). Nevertheless, the present study demonstrates that intrahemispheric communication between the DH and the BLA is required for the reconsolidation of context-response-cocaine associative memories that regulate drug context-induced cocaine-seeking behavior. Accordingly, we propose that cocaine-related associative memories undergo ANI-sensitive re-stabilization in the BLA, and the DH may contribute to the maintenance of PR-STM or the establishment of retrieval links in the BLA or elsewhere in the brain during the time of memory reconsolidation. The necessary communication between the BLA and DH may occur via sparse monosynaptic connections between the BLA and DH (Pikkarainen et al. 1999) or via multisynaptic connections that involve other brain regions. The entorhinal cortex may serve as a relay in this circuit as this brain region has reciprocal connections with both the BLA and DH (Finch et al. 1986; Witter et al. 1989, Van Groen and Wyss 1990; McDonald and Mascagni 1997; Fanselow and Dong 2010).

Time-dependent effects of post-reactivation BLA/DH disconnection on drug-context-induced cocaine-seeking behavior and implications for the treatment of drug addiction

Inhibition of memory reconsolidation is predicted to selectively impair the memory trace and, consequently, elicit prolonged interference with conditioned behavior (for review, see Nader 2003; Amaral et al. 2008), and this property is desirable from a treatment perspective. In fact, it has been suggested that disrupting the reconsolidation of maladaptive associative memories may be useful for the treatment of psychiatric disorders, including post-traumatic stress disorder, phobias, obsessive-compulsive disorder, and addictive behavior (Diergaarde et al. 2008; Taylor et al. 2009; Milton and Everitt 2010). In this respect, it is encouraging that BLA/DH disconnection attenuated overall drug context-induced cocaine-seeking behavior to a similar extent after a 21-d vs. overnight home cage stay and approximately two extinction training days, relative to VEH (Fig. 4B). Thus, memory reconsolidation inhibitors may open a therapeutic window by impairing memory traces that underlie the incentive motivational effects of drug-associated environmental stimuli even though it is unlikely they prevent the resumption of drug-taking behaviors if drug reinforcement contingencies are restored.

Interestingly, the inhibitory effects of BLA/DH disconnection on drug-context-induced cocaine-seeking behavior were apparent only after the first 20-min interval of the test session
relative to VEH treatment (Fig. 4D). It is unlikely that cocaine-seeking behavior during the first 20-min interval of the test session in the BLA/DH disconnection group reflected spontaneous recovery, the return of a previously extinguished response with time (Domjan 1998; Eisenberg et al. 2003; Bouton 2004), given that manipulations of the DH (Corcoran et al. 2005; Bevilacqua et al. 2007) or BLA (Fuchs et al. 2006; McLaughlin and Floresco 2007; Baldi and Bucherelli 2010) impair, rather than enhance, extinction learning. Rather, it probably signifies the maturation—thus, delayed availability—of alternate memory traces (McClelland et al. 1995; Frankland and Bontempi 2005; Frankland et al. 2006; Annaral et al. 2008), or the re-strengthening of memory traces weakened by ANI + B/M treatment in the absence of external cue exposure during abstinence. Consistent with the idea of residual memory traces, humans exhibit impaired cue-induced fear memory but intact declarative memory of CS-fear contingency following memory reconsolidation inhibition using beta adrenergic receptor antagonism (Kindt et al. 2009). Similar to declarative memories, the putative residual memories in the present study failed to elicit sustained motivated behavior.

The strengthening of drug-related associative memories may be a mechanism for incubation, the well-documented augmentation of drug-seeking behavior after a period of abstinence that has been implicated in the transition from casual drug use to compulsive drug-seeking and drug-taking behaviors (Tran-Nguyen et al. 1998; Grimm et al. 2001; Thomas et al. 2008). In support of this idea, repetitive reflection on drug-related memories predicts future increases in substance abuse symptoms in humans (Nolen-Hoeksema et al. 2007). Consistent with an incubation effect, the groups that remained in their home cages for 21 d following cocaine memory reactivation and were tested on approximately post-cocaine day 32 exhibited more robust context-induced cocaine-seeking behavior than overnight home cage controls (see Fig. 4B, inset). This incubation effect was modest relative to that observed in other studies (see Grimm et al. 2001; Lu et al. 2004), likely due to extensive extinction training (Berglind et al. 2007; Kelamangalath and Wagner 2009). Incubation manifested as impairment in the extinction of drug context-induced cocaine-seeking behavior during the nonreinforced test session (i.e., perseveration) following the 21-d vs. overnight home cage stay (see Fig. 4D). Remarkably, contralateral ANI + B/M treatment reversed the incubation-related perseveration in cocaine-seeking behavior. These data suggest that, during early withdrawal, the integrity of memory traces that encode context-response-cocaine associations may be necessary for the subsequent development of incubation, consistent with the idea that incubation may involve the strengthening of associative memory traces over time.

In conclusion, BLA/DH disconnection at the time of cocaine memory reconsolidation had a robust inhibitory effect on the motivational effects of a cocaine-paired environmental context when evaluated 18 d after initial memory consolidation and after extensive memory reconsolidation during the 10-d cocaine self-administration training regimen (also see Lee et al. 2006). Some recovery of cocaine-seeking behavior was observed following an extended drug-free period (i.e., 39 d after initial memory consolidation), likely due to the availability of new or residual cocaine-related associative memories. However, importantly, BLA/DH disconnection attenuated cocaine-seeking behavior even after the development of incubation. These findings confirm that the BLA and DH interact to control cocaine-related memory reconsolidation and drug context-induced cocaine-seeking behavior and support the idea that targeting memory reconsolidation to combat environmentally induced relapse may be a worthwhile treatment option for recovering drug addicts.

Materials and Methods

Animals

Male Sprague-Dawley rats (Charles-River, Wilmington, MA, n = 61) were maintained in a temperature- and humidity-controlled vivarium on a reversed light-dark cycle. Rats weighed between 275–300 g at the start of the experiment and were maintained on 20–25 g of rat chow per day with water available ad libitum. The housing and treatment of animals used in the study followed the National Research Council’s Guide for the Care and Use of Laboratory Rats (Institute of Laboratory Animal Resources on Life Sciences) and were approved by the Institutional Animal Care and Use Committee of the University of North Carolina at Chapel Hill.

Food training

To accelerate the acquisition of cocaine self-administration, rats were initially trained to press a lever under a fixed-ratio 1 schedule of food reinforcement (i.e., each active lever press resulted in the delivery of a 45-mg pellet [Noyes]) during a 16-h session overnight. Food training was conducted in standard sound-attenuated operant conditioning chambers (26 × 27 × 27 cm) (Coulbourn Instruments). During the session, active lever responses were reinforced with the delivery of food pellets while inactive lever responses had no programmed consequences. The contextual stimuli that were used during cocaine self-administration and extinction training were not present in the chambers during food training.

Surgery

Forty-eight hours after food training, rats were fully anesthetized with ketamine hydrochloride and xylazine (66.6 mg/kg and 1.33 mg/kg, i.p., respectively). Intravenous catheters were constructed in-house, as described previously (Fuchs et al. 2007). The catheter was inserted into the right jugular vein and ran subcutaneously to the back where it exited between the scapulae. Immediately after the catheterization surgery, rats were placed into a stereotaxic instrument (Stoelting). Twenty-six gauge stainless-steel guide cannulae (Plastics One) were aimed unilaterally at the right or left BLA (~2.7 mm AP, ± 5.2 mm ML, –6.8 mm DV, relative to bregma) and at the contralateral or ipsilateral DH (angled rostrally by 15° to accommodate the BLA cannula, –4.1 mm AP, ± 2.1 ML, –2.7 mm DV, relative to bregma). Stainless steel screws and transplastc cement secured the guide cannulae to the skull. Stylets (Plastics One) and Tygon caps sealed the guide cannulae and catheter, respectively, in order to prevent occlusion.

Rats were given 5 d of post-operative recovery before the start of the experiment. To maintain catheter patency during this time, the catheters were flushed through daily with 0.1 mL of an antibiotic solution of ceftazolin (10.0 mg/mL; Schein Pharmaceuticals) dissolved in heparinized saline (70 U/mL; Baxter Health Care Corp.) followed by 0.1 mL of heparinized saline (70 U/mL). During self-administration training, catheters were flushed through with 0.1 mL of heparinized saline (10 U/mL) before each session and with 0.1 mL of the ceftazolin solution and 0.1 mL of heparinized saline (70 U/mL) after each session. Catheter patency was assessed before the first self-administration session and periodically during the experiment, using propofol (1 mg/0.1 mL, i.v.; Eli Abbott Lab), which produces temporary loss of muscle tone when administered intravenously.

Cocaine self-administration training

Self-administration training was conducted in standard operant conditioning chambers configured to one of two distinctly different contexts. Context 1 contained a continuous red house light opposite to the active lever, intermittent pure tone (80 dB, 1 kHz; 2 sec on, 2 sec off), pine-scented air freshener strip (4.5 cm × 2 cm; Car Freshener Corp.), and a wire mesh floor (26 cm × 27 cm). Context 2 contained an intermittent white
Immediately after the memory reactivation session, rats received
intracranial manipulations. Active lever responses activated an
infusion pump for 2 sec. Each infusion was immediately
followed by a 20-sec time-out period, during which active lever
responses had no programmed consequences. Responses on the
other (inactive) lever were recorded but had no programmed con-
sequences. Training continued until rats reached a criterion of
≥10 cocaine infusions per session during at least 10 sessions.
Data collection and reinforcer delivery were controlled using
Graphic State Notation software version 2.102 (Coulbourn).

Extinction training
After reaching the acquisition criterion, rats received seven daily
2-h extinction training sessions. Rats that self-administered
cocaine in Context 1 were placed into Context 2 for extinction
training, and vice versa. During the extinction sessions, active
and inactive lever responses were recorded but had no pro-
grammed consequences. Immediately after the fourth extinction
session, rats were adapted to the intracranial microinfusion proce-
dure. To this end, stainless steel injection cannulae were inserted
into the guide cannulae to a depth of either 1 mm (DH) or 2 mm
(BLA) below the tip of the guide cannulae. The injector cannulae
remained in place for 4 min, but no fluid was infused during the
adaptation procedure.

Experiment 1: Effects of BLA/DH disconnection on cocaine
memory reconsolidation
Experiment 1 was designed to evaluate whether functional dis-
connection of the BLA and DH following cocaine memory reacti-
vation would impair subsequent drug context-induced cocaine
seeking. A schematic representing the experimental timeline is
provided in Figure 2A.

Memory reactivation
After the final day of extinction training, rats were re-exposed to
the cocaine-paired context for 15 min in order to destabilize
cocaine-related memories (Lewis 1979; Nader et al. 2000b;
Tronson and Taylor 2007). This session length was selected
because it is sufficient to reactivate cocaine-related associative
memories without producing significant behavioral extinction
(Fuchs et al. 2009). During the memory reactivation session, rats
were connected to the infusion apparatus, but fluids were not
infused, and responding on the active and inactive levers had
no programmed consequences.

Intracranial manipulations
Immediately after the memory reactivation session, rats received
a unilateral microinfusion of anisomycin (62.5 μg/0.5 μL) into
the left or right BLA plus a unilateral microinfusion of the GABA
agonists baclofen/muscimol (1.0/0.01 mM/0.5 μL) into the con-
tralateral or ipsilateral DH. The dose of ANI used was selected
based on our previous research demonstrating that when microin-
fusion bilaterally into the BLA, but not the overlying posterior
caudate-putamen (pCPu), this dose was sufficient to disrupt
cocaine memory reconsolidation in our model (Fuchs et al.
2009). While tetrodotoxin was used in our previous study to
demonstrate the involvement of the DH but not the overlying trunk
region of the somatosensory cortex (SStr), in cocaine memory
reconsolidation (Ramirez et al. 2009), B/M was used in the present
disconnection study in order to selectively inhibit neural activity
within the DH while sparing fibers of passage (van Duuren et al.
2007). The dose of B/M was selected based on an earlier BLA/
DH disconnection study (Fuchs et al. 2007). Vehicle control
groups received phosphate buffered saline (0.5 μL) unilaterally
into the BLA plus the contralateral or ipsilateral DH. Assignment
to treatment conditions was counterbalanced based on previous
cocaine intake. During the microinjection procedure, the injec-
tion cannulae were connected to Hamilton syringes (Hamilton
Co.) that were mounted on a microdrive pump (KD Scientific).
Microinfusions were delivered over 2 min, and the injection can-
nulae were left in place for 1 min before and after the microinfu-
sion in order to limit drug diffusion, as described previously
(Fuchs et al. 2007).

Extinction training and test of drug context-induced
cocaine seeking
Starting on the day following the memory reactivation session, rats
received additional daily 2-h extinction training sessions until
they reached an extinction criterion (i.e., <25 active lever
responses per session on a minimum of two consecutive days).
Twenty-four hours later, rats were returned to the cocaine-paired
context for a 2-h test of cocaine-seeking behavior. During the
test session, active and inactive lever presses were recorded but
had no programmed consequences.

General motor activity testing
Intracranial manipulations can alter cocaine-seeking behavior by
impairing general motor activity. This was unlikely in the present
study since testing occurred at a minimum of 72 h following the
intracranial manipulation. Nonetheless, the possible protracted
effects of contralateral and ipsilateral ANI + B/M and VEH treat-
ments on motor activity were assessed 24 h after the reinstate-
ment test in Experiment 1. The general motor activity test took
place in a novel Plexiglas chamber (42 × 20 × 20 cm) that was
equipped with an array of eight photodetectors. A computerized
activity system (San Diego Instruments) recorded photobeam
breaks resulting from the movement of rats in the chamber during
a 2-h session.

Experiment 2: Effects of BLA/DH disconnection in the
absence of explicit cocaine memory reactivation
The memory reconsolidation theory posits that reconsolidation
inhibits selectively targeted memories that have been rendered
labile by reactivation (Nader et al. 2000b; Alberini et al. 2006;
Tronson and Taylor 2007). Experiment 2 was designed to evaluate
whether the effect observed in Experiment 1 would be similarly
observed in the absence of explicit cocaine memory reactivation.
The experimental protocol was identical to that in Experiment 1
except that the groups were placed into a novel, unpaired context
for 15 min prior to receiving ipsilateral or contralateral ANI + B/
M or VEH + VEH microinfusions into the BLA and DH, respec-
tively. The unpaired context contained continuous white stimu-
lus lights above each lever, a continuous red house light
opposite to the active lever, a continuous complex tone (80 dB,
alternating between 1, 1.5, and 2.5 kHz at 1 sec intervals), a
citrus-scented air freshener strip (4.5 × 2 cm, Locasmarts LLC),
and ceramic tile flooring (26 cm × 27 cm). A schematic represent-
ing the experimental timeline for Experiment 2 is provided in
Figure 3A.

Experiment 3: Time-dependent effects of post-memory
reactivation BLA/DH disconnection on drug
context-induced cocaine seeking
Genuine memory reconsolidation deficits are characterized by the
loss or impairment of the memory trace, and in turn, long-lasting
behavioral deficit (Nader and Wang 2006). Experiment 3 was
designed to evaluate the effects of BLA/DH disconnection, admin-
istered following re-exposure to a cocaine-paired context, on the
ability of the cocaine-paired context to restate cocaine-seeking
behavior after an extended drug-free period.
All protocols in this experiment were identical to those used in Experiments 1 and 2, except that rats were assigned to stay in their home cages for 21 d following the memory reactivation session and intracranial microinjections. During the home cage stay, rats were handled regularly. A schematic representing the experimental timeline is provided in Figure 4A. The contralateral BLA/ DH-cannulated groups from Experiment 1 served as 0-d (over-night) home cage control groups in Experiment 3.

Histology

After the last experimental session, rats were overdosed with ketamine hydrochloride and xylazine (66.6 and 1.3 mg/kg, i.v., or 199.8 and 3.9 mg/kg, i.p., respectively, depending on catheter patency). They were then transcardially perfused with 1× phosphate-buffered saline ( Fisher Scientific) and 10% formaldehyde solution (Sigma). Brains were dissected out and stored in 10% formaldehyde solution until they were sectioned in the coronal plane at a thickness of 75 μm using a vibratome. The sections were mounted onto gelatin-coated slides and stained using cresyl violet (Kodak). Cannula placements were verified using light microscopy. The most ventral portion of each cannula tract was mapped onto schematics of appropriate plates from the rat brain atlas ( Paxinos and Watson 1997).

Data analysis

Separate ANOVAs were conducted to test for possible pre-existing differences in cocaine intake as well as active and inactive lever responding during cocaine self-administration training (mean of last 3 d), extinction training (day 1, day 7), and during the memory reactivation session for the groups of rats in Experiments 1, 2, and 3. In these ANOVAs, group was included as a between-subjects factor, and time (extinction day 1, extinction day 7) was included as a within-subjects factor, as appropriate. Pearson r correlation coefficients were calculated to examine the relationship between active lever responding during the memory reactivation session and during the test of drug context-induced cocaine-seeking behavior.

Separate mixed-factorial ANOVAs were conducted to examine the effects of post-reactivation manipulations on the number of days required to reach the extinction criterion, on active and inactive lever responses on the test days in the cocaine-paired and extinction contexts (last extinction session before the test in the cocaine-paired context), and on motor activity. In these ANOVAs, treatment (VEH + VEH, ANI + B/M), surgery type (ipsilateral, contralateral), and home cage condition (0 d, 21 d) were included as between-subjects factors, while context (extinction, cocaine-paired) and time (six 20-min intervals) were included as within-subjects factors as appropriate. Significant main and interaction effects were further probed using post-hoc Tukey tests. In addition, the potential hemispheric laterality of significant effects was examined using t-tests separately because the variables BLA hemisphere and DH hemisphere were not orthogonal. Alpha was set at 0.05.

Acknowledgments

We thank Albert Newsome for excellent technical assistance and Drs. Donna Ramirez and Amy Arguello for comments on an earlier version of this manuscript.
