Hollow mesoporous silica nanoparticle (HMSN) has recently gained increasing interests due to their tremendous potential as an attractive nano-platform for cancer imaging and therapy. However, possibly due to the lack of efficient in vivo targeting strategy and well-developed surface engineering techniques, engineering of HMSN for in vivo active tumor targeting, quantitative tumor uptake assessment, multimodality imaging, biodistribution and enhanced drug delivery have not been achieved to date. Here, we report the in vivo tumor targeted positron emission tomography (PET)/near-infrared fluorescence (NIRF) dual-modality imaging and enhanced drug delivery of HMSN using a generally applicable surface engineering technique. Systematic in vitro and in vivo studies have been performed to investigate the stability, tumor targeting efficacy and specificity, biodistribution and drug delivery capability of well-functionalized HMSN nano-conjugates. The highest uptake of TRC105 (which binds to CD105 on tumor neovasculature) conjugated HMSN in the 4T1 murine breast cancer model was 10%ID/g, 3 times higher than that of the non-targeted group, making surface engineered HMSN a highly attractive drug delivery nano-platform for future cancer theranostics.
MSN needs to be further improved and the highest tumor uptake was not ideal (~6 percentage injected dose per gram of tissue [%ID/g]).

Here, we report the in vivo tumor targeted positron emission tomography (PET)/near-infrared fluorescence (NIRF) dual-modality imaging and enhanced drug delivery of HMSN by using a generally applicable surface engineering method. The anti-cancer drug loading capacity of HMSN was found to be 3–15 times higher than previously reported MSN. By using CD105 (also known as endoglin, which is a validated marker for tumor angiogenesis and almost exclusively expressed on proliferating tumor endothelial cells\textsuperscript{13,14}) based tumor vasculature targeting strategy, we achieved over 3-fold higher tumor uptake (~10%ID/g at 4 h post-injection [p.i.]) in targeted group when compared with the non-targeted group (~3%ID/g at 4 h p.i.). Systematic in vitro and in vivo studies were performed to investigate the stability, targeting efficacy and specificity, biodistribution and drug delivery capability of well-functionalized HMSN nano-conjugates. With the growing interests in using HMSN as a drug delivery nano-platform, this study may pave the way for future cancer theranostics using HMSN, since silica is generally regarded as safe (GRAS) by the Food and Drug Administration (FDA)\textsuperscript{3}.

Results

Synthesis and characterization. Uniform HMSN with an average particle size of 150 nm was synthesized following the literature procedures with improved Na\textsubscript{2}CO\textsubscript{3}-etching process\textsuperscript{16}. Generally, three steps were involved. Firstly, uniform ~100 nm sized dense silica (dSiO\textsubscript{2}) nanoparticles were prepared as hard templates using a modified Stöber method\textsuperscript{17}. Secondly, shell thickness controllable MSN layer was coated on each dSiO\textsubscript{2} using cetyltrimethylammonium chloride (i.e. CTAC) as the soft templates at 80°C, forming dSiO\textsubscript{2}@[MSN(CTAC)] (Figure 1a, dark core represents dSiO\textsubscript{2} core, while lighter shell is MSN). Thirdly, as-synthesized dSiO\textsubscript{2}@[MSN(CTAC)] together with free CTAC, forming uniform HMSN(CTAC) after the re-adding of CTAC, and the ethching process could be easily completed within 30 min possibly due to the increased CTAC concentration. Figure 1b shows the representative transmission electron microscopy (TEM) image of as-prepared HMSN(CTAC) with oriented mesoporous shell structures. The surfactant CTAC was later removed via an extraction process by stirring HMSN(CTAC) in 1 wt% solution of NaCl in methanol\textsuperscript{18}. The pore size of HMSN was 2-3 nm, similar to that of MSN as we reported previously\textsuperscript{13}. The diameter of hollow space was ~100 nm, and the thickness of MSN shell was measured to be ~25 nm. Both hollow cavity and MSN shell thickness are readily tunable. For example, using smaller size dSiO\textsubscript{2} (~50 nm), which could be synthesized in a water-in-oil reverse microemulsion\textsuperscript{19}, uniform HMSN with a smaller cavity inside (~50 nm) and thinner MSN shell (~7.5 nm) outside could also be synthesized (Figure S1).

As proposed by Zheng et al., selective etching of dSiO\textsubscript{2} core and re-deposition of the soluble silicate species are both important steps during the formation of HMSN\textsuperscript{20}. Cationic surfactants (in our case CTAC) play vital roles in such etching-redeposition mechanism\textsuperscript{16}. During the etching process, positively charged cetyltrimethylammonium cations (CTA\textsuperscript{+}) will first absorb to the surface of dSiO\textsubscript{2}@[MSN(CTAC)] via electronic attraction. Subsequently, with the presence of Na\textsubscript{2}CO\textsubscript{3} in the solution and CTAC in the MSN shell, selective etching of silica from the dSiO\textsubscript{2} core starts and will be accelerated by the surrounding free CTAC, forming uniform HMSN(CTAC) after the redeposition process.

We also found that, to selectively etch out the dSiO\textsubscript{2} core and leave the MSN shell intact, the CTAC concentration, etching temperature and etching time should be tightly-controlled. Only dSiO\textsubscript{2} will be obtained, and all the MSN shell will be etched away if the concentration of CTAC was kept at below 6.25 mg/mL (Figure S2a). Increasing the CTAC concentration up to 66.7 mg/mL will result in uniform HMSN only when etching is done in a water bath with a mild temperature (i.e. 50°C) for a relatively short time (e.g. 30–60 min), as shown in Figure S2b. Too high etching temperature (e.g. 80°C) and too long etching time will easily cause over-etching of HMSN, leaving aggregated nanoparticles with highly rough surfaces (Figure S2d,e,f).

Surface engineering plays a vital role in in vivo applications of nanoparticles, including HMSN. Figure 2 shows the major steps involved in the synthesis of multifunctional HMSN starting from

---

Figure 1 | Synthesis of HMSN and HMSN-ZW800-TRC105. (a) TEM image of dSiO\textsubscript{2}@MSN. Upper left & right: a scheme and TEM image of single dSiO\textsubscript{2}@MSN (dark core represents dSiO\textsubscript{2} core, while lighter shell is MSN). (b) TEM image of HMSN. Upper left & right: a scheme and TEM image of single HMSN. (c) TEM image of HMSN-ZW800-TRC105. Upper left & right: a scheme and TEM image of single HMSN-ZW800-TRC105.
hard template of dSiO$_2$ (1). After the generation of uniform HMSN (3), the nanoparticles were surface modified with amino groups (-NH$_2$) to obtain HMSN-NH$_2$ (4) before further bio-conjugations. Anti-cancer drugs (i.e. DOX) were then loaded, followed by NIR dye (i.e. ZW800) and $^{64}$Cu chelator (i.e. NOTA) conjugations, forming NOTA-HMSN(DOX)-ZW800 (5). Afterward, nano-conjugate was PEGylated with SCM-PEG$_{5k}$-Mal to render its stability in biological buffers (e.g. PBS), forming NOTA-HMSN(DOX)-ZW800-PEG-Mal (6). Then, thiolated anti-CD105 antibody (i.e. TRC105-SH) was conjugated to the nanoparticle to obtain NOTA-HMSN(DOX)-ZW800-PEG-TRC105 (7). Lastly, PET isotope $^{64}$Cu ($t_{1/2} = 12.7$ h) was used to label the nanoparticle, forming $^{64}$Cu-NOTA-HMSN(DOX)-ZW800-PEG-TRC105 (8).

A representative TEM image of HMSN-ZW800-TRC105 is shown in Figure 1c, where no obvious morphology change of HMSN could be observed after multi-step surface modification. The final nano-conjugate could be well-dispersed in phosphate buffered saline (PBS). Average size of HMSN-ZW800-TRC105 was found to be $\sim 150$ nm, which is slightly smaller than the Z-average size (i.e. 194.4 nm) measured by dynamic light scattering (DLS). Average size of HMSN-ZW800-TRC105 was found to be $\sim 150$ nm, which is slightly smaller than the Z-average size (i.e. 194.4 nm) measured by dynamic light scattering (DLS). Figure S3 also presents the size distribution of HMSN-ZW800-TRC105, acquired by DLS. Slightly negatively charged surface ($-5.1 \pm 0.9$ mV) of HMSN-ZW800-TRC105 was also observed.

Zwitterionic NIR fluorophore ZW800 (also named as ZW800-1) has recently been demonstrated as a better NIR dye (Ex = 745 nm, Em = 800 nm) for providing a significantly improved signal-to-background...
ratio during in vivo image-guided surgery, in comparison with traditional dyes such as Cy5.5 and IRDye800CW. Therefore, ZW800-NHS ester was covalently conjugated to the outer surface of HMSN-NH₂ to render the nanoparticle NIRF imaging capability. To avoid the possible dye-dye self-quenching, the optimal ratio between HMSN and ZW800 was carefully investigated (Figure 3). The lowest degree of ZW800 quenching (~4.8%) was observed when keeping the mole ratio as low as 1:2, where up to 81.4% conjugation efficiency was achieved with each HMSN covered by approximately 1.6 ZW800 dyes (Figure 3a, Table S1). Increasing the amount of dyes while keeping that of HMSN unchanged would increase the number of dye per HMSN to larger than 8, as shown in Table S1, however it also caused severe dye-dye quenching: About 74% and 92% degree of quenching were estimated when fixing the ratio to be 1:10 and 1:20, respectively (Figure 3b,c and Table S1). Therefore, the optimized ratio of 1:2 was used in the following in vivo tumor targeted imaging studies.

**In vitro CD105 targeting of HMSN-ZW800-TRC105**. Before the in vivo tumor targeted imaging, human umbilical vein endothelial cells (HUVECs, CD105 positive) and MCF-7 human breast cancer cells (CD105 negative) were used for flow cytometry studies to confirm the in vitro CD105 targeting efficiency of the HMSN-ZW800-TRC105. Due to the lack of NIR excitation light source in BD FACS Calibur four-color analysis cytometer (equipped with 488 and 633 nm lasers), NHS-fluorescein was conjugated to the surface of nanoparticles to facilitate such investigation. The flow cytometry results from Figure 4a indicated that incubation with fluorescein conjugated HMSN-ZW800-TRC105 (50 nM, targeted group) could significantly enhance the mean fluorescence intensity of HUVECs, while treatment with fluorescein conjugated HMSN-ZW800 (50 nM, non-targeted group), or fluorescein conjugated HMSN-ZW800-TRC105 with a blocking dose of TRC105 (500 µg/mL, blocking group), only gave minimal fluorescence enhancement. In contrast, incubating fluorescein conjugated HMSN-ZW800-TRC105 or fluorescein conjugated HMSN-ZW800 with MCF-7 cells only showed background fluorescence level for all groups (Figure 4b), demonstrating low non-specific binding of functionalized HMSN conjugates in CD105 negative cells. Taken together, these results confirmed the specificity and sensitivity of the CD105 targeted HMSN-ZW800-TRC105 system for in vivo tumor targeting.

![Figure 3](image3.png) **Dye-dye self-quenching study.** The molar ratio of HMSN to ZW800 was fixed to be (a) 1:2, (b) 1:10, (c) 1:20. Digital photos of HMSN-ZW800 showing nanoparticles in water before (Lane 1) and after centrifugation (Lane 2). (Lane 3) Optical imaging of HMSN-ZW800 with different amount of dye per nanoparticle. (Lane 4) Optical imaging of ZW800 dye in the supernatant after each reaction, indicating unconjugated ZW800. Images were acquired using an IVIS spectrum in vivo imaging system (Ex = 745 nm, Em = 800 nm).

![Figure 4](image4.png) **In vitro CD105 targeting.** Flow cytometry analysis of fluorescein conjugated HMSN-ZW800-TRC105 in (a) HUVEC (CD105 positive) and (b) MCF-7 (CD105 negative) cells after 30 min incubation and subsequent washing. For non-targeted group, same concentration of fluorescein conjugated HMSN-ZW800 was used. In blocking group, free TRC105 (500 µg/mL) was added before adding fluorescein conjugated HMSN-ZW800-TRC105. All incubation time were kept the same as 30 min.
PET is highly sensitive, quantitative, clinically relevant, and has excellent tissue penetration of signal\textsuperscript{11–24}. Labeling nanoparticles with positron-emitting radionuclides has been generally recognized as the most accurate means for non-invasive evaluation of their biodistribution and pharmacokinetics\textsuperscript{25–28}. For in \textit{vivo} tumor targeted PET imaging, NOTA-HMSN-ZW800-TRC105 was labeled with $^{64}$Cu and purified using PD-10 columns with PBS as the mobile phase. The radioactivity fractions (typically elute between 3.0 and 4.0 mL) were collected for further \textit{in vivo} experiments. A typical size exclusion column chromatography profile is provided in Figure S4. Inset in Figure S4 also shows the PET and NIRF imaging of fraction 3.0–3.5 mL, demonstrating the successful synthesis of $^{64}$Cu-HMSN-ZW800-TRC105.

Since PET imaging detects the radioisotopes (e.g. $^{64}$Cu in this work) rather than the HMSN conjugates per se, excellent \textit{in vivo} stability is a prerequisite for PET to truly reflect the \textit{in vivo} distribution of $^{64}$Cu-HMSN-ZW800-TRC105. Serum stability study (Figure S5) of $^{64}$Cu-HMSN-ZW800-TRC105 showed that over 99% of $^{64}$Cu remained intact within $^{64}$Cu-HMSN-ZW800-TRC105 over a 24 h incubation period in whole mouse serum at 37°C while shaking, which indicates high stability of as-synthesized $^{64}$Cu-HMSN-ZW800-TRC105.

\textit{In vivo} tumor targeted PET imaging were then carried out in 4T1 murine breast tumor-bearing mice, which express high level of CD105 on the tumor neovasculature\textsuperscript{14,15}. Each mouse was injected with 800 pmol of ZW800. NIRF imaging was also carried out. Each 4T1 tumor-bearing mouse was first shaved and injected with HMSN-ZW800-TRC105 with 800 pmol of ZW800. Similar time points (i.e. 0.5, 4, 20, 24 h p.i.) as that of PET imaging studies were chosen for serial optical imaging to show the \textit{in vivo} biodistribution patterns of mice from targeting, non-targeting and blocking groups (Figure 5). Quantitative data obtained from region-of-interest (ROI) analysis of these PET images are also shown in Table S2–S4.

The accumulation of $^{64}$Cu-HMSN-ZW800-TRC105 in the 4T1 tumor was found to be $8.5 \pm 1.1$%ID/g at 0.5 h p.i. and peaked at $9.9 \pm 0.9$%ID/g at 4 h p.i., as shown in Figure 5a,6a,S6 and Table S2 (n = 4). In contrast, without the conjugation of TRC105 (i.e. passive targeting alone), the 4T1 tumor uptake of $^{64}$Cu-HMSN-ZW800 was found to be only one third of the targeted group at all of the time points examined (n = 4; Figure 5b, Table S3), indicating that TRC105 conjugation could be the controlling factor for enhanced tumor accumulation of $^{64}$Cu-HMSN-ZW800-TRC105. To further confirm CD105 targeting specificity of $^{64}$Cu-HMSN-ZW800-TRC105 in \textit{vivo}, blocking studies were also performed. Administration of a blocking dose (1 mg/mouse) of free TRC105 at 1 h before $^{64}$Cu-HMSN-ZW800-TRC105 injection could significantly reduce the tumor uptake to $4.1 \pm 1.7$ and $5.5 \pm 2.2$%ID/g at 0.5 and 4 h p.i., respectively (n = 3, Figure 5c, Table S4), clearly demonstrating CD105 specificity of $^{64}$Cu-HMSN-ZW800-TRC105 in \textit{vivo}. Figure 6c also summarizes the comparison of 4T1 tumor uptake of 3 groups at different time points, where $^{64}$Cu-HMSN-ZW800-TRC105 shows the highest tumor uptake throughout the study period.

Besides significantly improved tumor targeting efficacy, the tumor-to-muscle (T/M) ratios increased as well. As shown in Figure 5b, T/M value of the targeted group was estimated to be $9.0 \pm 1.7$ at 0.5 h p.i., and increased up to $13.7 \pm 0.6$ at 4 h p.i., which is significantly higher than that of non-targeting and blocking groups (Figure S7, Table S6–S7). Similar as what we have observed previously with $^{64}$Cu-MSN-TRC105\textsuperscript{22}, besides tumor accumulation, most of $^{64}$Cu-HMSN-ZW800-TRC105 nano-conjugates were taken up by the reticuloendothelial system (RES) with liver uptake found to be $27.8 \pm 1.6$%ID/g at 0.5 h p.i. and decreased gradually to $15.4 \pm 1.1$%ID/g at 24 h p.i. (n = 4; Figure 6a, Table S2), which was validated by the \textit{ex vivo} biodistribution study (Figure 6d).

Engineering of HMSN to integrate two or more imaging modalities into one nanosystem has become a recent trend, which could provide complementary and more accurate information about the pharmacokinetics of HMSN \textit{in vivo}\textsuperscript{9}. Generally speaking, optical imaging is inexpensive, widely available, and highly sensitive for superficial tissues, which has been extensively used for monitoring various molecular/biological events in cells and small animal models\textsuperscript{29,30}. Although various strategies (e.g. organic dye doping, fluorescent nanoparticle encapsulation, \textit{etc}.) have been developed to engineer MSNs for optical imaging applications \textit{in vitro} and \textit{in vivo}, very few reports about the engineering of HMSN for \textit{in vivo} targeted optical imaging exist in the literature.

With the presence of optimized number of ZW800 on the surface of each HMSN nano-conjugate, the \textit{in vivo} NIRF imaging was also carried out. Each 4T1 tumor-bearing mouse was first shaved and injected with HMSN-ZW800-TRC105 with 800 pmol of ZW800. Similar time points (i.e. 0.5, 4, 20, 24 h p.i.) as that of PET imaging studies were chosen for serial optical imaging using the IVIS Spectrum system ($Ex = 745$ nm, $Em = 800$ nm). Figure 7 shows the \textit{in vivo} NIRF images of mice from 3 groups. Significantly higher optical intensity of tumor (marked with red circle) from targeted group could be clearly seen (Figure 7a–c), and was confirmed by the \textit{ex vivo} imaging (Figure 7d–f, right lane). For all 3 groups, tumor signals decreased over time, possibly due to the wash-out of nano-conjugates in vivo. \textit{Ex vivo} imaging of major organs, e.g. liver (L), spleen (S), lung (Lu), kidney (K), heart (H) and tumor (T), showed similar distribution patterns as what has been shown in Figure 6d, with liver and spleen being the major nanoparticle uptake organs.

\textbf{Enhanced \textit{in vivo} tumor targeted drug delivery.} Although MSN has been considered as a drug delivery nano-platform for over 10 years\textsuperscript{31}, it was not until recently that the first example of quantitative assessment of tumor targeting efficacy and \textit{in vivo} enhanced drug delivery.
delivery using TRC105 conjugated MSN(DOX) was demonstrated by our group\textsuperscript{13}. In this work, we demonstrated that HMSN could become a more attractive nanocarrier for future drug delivery applications.

In comparison with the DOX loading capacity in MSN (i.e. 71.6–481.6 mg/g), with the presence of hollow cavity inside HMSN, a significantly improved (about 3–15 times higher) drug loading capacity, up to 1129.2 mg/g, was achieved (Figure S8a). The successful loading of DOX was further supported by the UV-vis absorbance spectra of HMSN(DOX), which exhibited the characteristic absorption peak at around 480 nm (Figure 8a, red line). DOX is known to be intrinsically pH sensitive\textsuperscript{32}. Due to the protonation of silanols (\(-\text{Si-OH}\)) in HMSN with the decrease of pH, electrostatic interaction between DOX and HMSN will be decreased, causing the dissociation of DOX from the silica surface and mesoporous channels. A pH-sensitive DOX release profile was also observed in HMSN(DOX), where shows a faster DOX release rate at acidic condition (pH 5.0) than that at neutral condition (pH 7.4, Figure 8b). Besides loading one type of hydrophilic anti-cancer drug, e.g. DOX, we also demonstrated here that HMSN could be a promising nanocarrier for loading certain hydrophobic drugs, such as Sunitilb (SUN, Figure S9), as well as double-loading with both SUN and DOX (Figure S10).

As a proof-of-concept, we further demonstrated the feasibility of enhanced tumor targeted drug delivery in vivo using TRC105 conjugated HMSN(DOX), denoted as HMSN(DOX)-TRC105, after i.v. injection in 4T1 tumor-bearing mice (HMSN dose: 10 mg/kg, DOX dose: 6.5 mg/kg). Half an hour after injection of HMSN(DOX)-(w/o)-TRC105 (w/o denotes with and without), the major organs were collected and imaged in the IVIS system (Ex = 465 nm; Em = 580 nm) to detect the presence of DOX, as shown in Figure 8c, d. It is important to note that due to different absorption/scattering behaviors of DOX in various tissues, optical signal intensities from different organs may not accurately reflect the absolute uptake level of injected HMSN(DOX)-(w/o)-TRC105. For example, although liver is the dominant organ for HMSN nano-conjugates accumulation, as evidenced in our PET/NIRF imaging and biodistribution studies (Figure 5, 6d, and 7), only weak optical signal could be observed based on ex vivo optical imaging because of its dark color.
and strong absorbance of visible DOX fluorescence (Figure 8d). In contrast, due to the much lighter color of tumor tissue, dominant optical signal from DOX could be observed in mice injected with HMSN(DOX)-TRC105, which is significantly stronger than the control group without TRC105 conjugation. Therefore, the significantly enhanced tumor targeting efficiency and drug (or multiple drugs) loading capacity will make antibody conjugated HMSN a highly attractive nano-platform for future cancer targeted imaging and therapy.

**Discussion**

Although molecular imaging of functionalized HMSN using imaging techniques, such as MRI\(^1\), optical imaging\(^2\) and ultrasound\(^3\), has been reported previously\(^4\), to date most of the studies have been primarily focused on optimization of nanoparticle synthesis. To the best of our knowledge, no in vivo tumor active-targeted PET imaging, quantitative tumor uptake, and biodistribution studies of HMSN have been reported. By surface engineering of uniform HMSN with radioisotopes (i.e. \(^{64}\)Cu), NIR dyes (i.e. ZW800) and CD105 targeting antibodies (i.e. TRC105), we reported here the first example of in vivo tumor vasculature targeted PET/NIRF dual-modal imaging of \(^{64}\)Cu-HMSN-ZW800-TRC105. An average of 3-fold enhancement of tumor accumulation was achieved in targeted group when compared with the non-targeted group. The CD105 specific targeting was further confirmed with blocking studies both in vitro and in vivo. It is also worthy to mention that the highest 4T1 tumor uptake of \(^{64}\)Cu-HMSN-ZW800-TRC105 (9.9 ± 0.9%ID/g at 4 h p.i., n = 4) was nearly 2 times higher than our previously reported \(^{64}\)Cu-MSN-TRC105 (5.9 ± 0.4%ID/g at 5 h p.i., n = 3)\(^13\), as shown in Figure S8b, resulting in remarkable enhancement in targeting efficacy as well as T/M ratio (13.7 ± 0.6 at 4 h p.i. vs 6.2 ± 1.8 at 5 h p.i.)\(^13\).

Meanwhile, although tumor vasculature targeting has recently been demonstrated to be a versatile strategy for many well-functionalized nanomaterials regardless of tumor type\(^38\), the absolute level of tumor accumulation for most of the nanomaterials investigated to date is still relatively low, typically in the range of 3–6%ID/g, significantly lower than that of liver uptake (usually 20–30%ID/g or higher for most of the nanomaterials upon i.v. injection). To the best of our knowledge, \(^{64}\)Cu-HMSN-ZW800-TRC105 is one of the very few vasculature targeted nanoparticles (another sample is RGD peptide conjugated single-walled carbon nanotubes which target integrin \(\alpha_v\beta_3\)\(^38\)) that could have about 10%ID/g of in vivo tumor uptake. Although we believe surface engineering of nanoparticles could play

---

a vital role, elucidating the exact reasons behind such remarkably enhanced tumor uptake requires systematic side-by-side tumor uptake comparison of well-engineered HMSN with varied particle size, morphology, surface charge, antibody density, etc., which deserves comprehensive investigation in the future. Considering the presence of large drug reservoir (i.e. hollow space) inside each HMSN, TRC105 conjugated HMSN might become a highly attractive drug delivery platform for future cancer theranostics.

In conclusion, we reported the engineering of uniform HMSN for remarkably enhanced in vivo tumor vasculature targeted PET/NIRF dual-modality imaging and enhanced drug delivery. Uniform and size-controllable HMSN was synthesized with a modified hard-templating method, which were subjected to a generally applicable surface engineering process, including amino groups functionalization, anti-cancer drug loading, NIR dye and NOTA linkages, PEGylation, antibody conjugation and radiolabeling, forming \(150 \text{ nm sized mono-disperse } ^{64}\text{Cu-HMSN(DOX)-ZW800-TRC105} \) nano-conjugates. The optimal ratio between HMSN and ZW800 was also carefully investigated to avoid the self-quenching effect, and found to be 1:2 with less than 5% of quenching. Systematic in vitro and in vivo studies were performed to investigate the stability, targeting efficacy and specificity, biodistribution and drug delivery capability of well-modified HMSN nano-conjugates. Quantitative PET imaging study showed an over 3-fold higher of tumor uptake in the targeted group when compared with the non-targeted group, demonstrating that \(^{64}\text{Cu-HMSN-ZW800-TRC105} \) is one of the very few vasculature targeting nanoparticles with high (\(>10\%\text{ID/g} \)) tumor uptake. Furthermore, with the presence of hollow space inside HMSN, 3–15 times higher of DOX loading capacity has also been achieved when compared with MSN, with the highest loading capacity estimated to be 1129.2 mg/g. In vivo enhanced DOX delivery was also demonstrated in 4T1 tumor-bearing mice. Take together these results, active tumor targeting and drug delivery of functionalized HMSN may pave the way for further in vivo targeted cancer therapeutic studies as well as potential clinical translational of this promising type of nano-platform, since silica is generally regarded as safe by the FDA.

**Methods**

**Synthesis of uniform HMSN.** Uniform HMSN with an average particle size of 150 nm was synthesized following the literature procedure with improved Na\(_2\)CO\(_3\)-etching process\(^{16}\). Three major steps were involved in the synthesis of HMSN. Firstly, synthesis of uniform \(100 \text{ nm sized } \text{dSiO}_2 \) using a modified Stoèber method\(^{17}\). In a typical synthesis, 35.7 mL of absolute ethanol was mixed with 5 mL water and 0.8 mL of ammonia and stirred for 5–10 minutes at room temperature. Then 1 mL of TEOS was added and the mixture was allowed to react at room temperature for 1 h. Afterward, \(\text{dSiO}_2 \) nanoparticles was washed with water and ethanol and suspended in 20 mL of water.

Secondly, synthesis of \(\text{dSiO}_2@\text{MSN} \). CTAC (2 g) and TEA (20 mg) were dissolved in 20 mL of high Q water and stirred at room temperature for 1 h. Then, 10 mL of...
**Synthesis of HMSN-NH₂** To functionalize the HMSN surface with –NH₂ groups, an synthetized HMSN was first dispersed in 20 mL of absolute ethanol, followed by addition of 1 mL of APS. The system was stirred for 1 h and the concentration of –NH₂ groups (nmol/mL) was measured using a Kaiser test kit.

**Synthesis of NOTA-HMSN-ZW800-PEG-TRC105** To conjugated HMSN with ZW800, 2 nmol of ZW800 was mixed with HMSN-NH₂ (with ~100 nmol of –NH₂ groups), and reacted for 2 h at room temperature (pH 8.5–9.0) to form HMSN-ZW800. Then, p-SCN-Bn-NOTA (400 nmol) of SCM-PEG5k-Mal was added and reacted for another 1 h, resulting in addition of 1 mL of APS. The system was sealed and kept at 86–90 °C in a water bath for 24 h. Afterward, the mixture was centrifuged and washed with ethanol for several times to remove the residual APS. The HMSN-NH₂ could be well-dispersed in water, and the concentration of –NH₂ groups (nmol/mL) was measured using a Kaiser test kit.

**PET/NIRF imaging and biodistribution studies.** All animal studies were conducted under a protocol approved by the University of Wisconsin Institutional Animal Care and Use Committee. PET and PET/CT scans at various time points p.i. using a microPET/MI PET/CT Environment model scanner (Siemens Medical Solutions USA, Inc.), image reconstruction, and ROI analysis of the PET data were performed similar as described previously43,44. Quantitative PET data were presented as %ID/g. Tumor-bearing mice were each injected with 5–10 MBq of 64Cu-NOTA-HMSN-ZW800 via tail vein before serial PET scans. Another group of three 4T1 tumor-bearing mice were each injected with 1 mg of unlabeled TRC105 at 1 h before 64Cu-HMSN-ZW800-TRC105 administration to evaluate the CD105 targeting specificity of 64Cu-HMSN-ZW800-TRC105 in vivo (i.e. blocking experiment).

After the last PET scans at 24 h p.i., biodistribution studies were carried out to confirm that the %ID/g values based on PET imaging accurately represented the radioactivity distribution in tumor-bearing mice. The radioactivity in the tissue was measured using a gamma-counter (Perkin-Elmer) and presented as %ID/g (mean ± SD).

For in vivo NIRF imaging, each 4T1 tumor-bearing mouse was injected with 0.5 nmol of HMSN-ZW800-TRC105 (targeted group) with the amount of ZW800 estimated to be ~800 pmol. The mouse was then imaged using an IVIS Imaging System (Ex = 745 nm, Em = 800 nm) at different time points. At 24 h p.i., mouse was sacrificed for ex vivo NIRF imaging. For non-targeting and blocking groups, mice were injected with the same amount of HMSN-ZW800 and HMSN-ZW800-TRC105 (tops with CD105), respectively.

**In vivo enhanced drug delivery.** HMSN(DOX)-TRC105 was first prepared. Typically, 0.4 mg of HMSN-NH₂ was first loaded with DOX, and then went through same PEcyclation and TRC105 conjugation, as described previously. For in vivo enhanced drug delivery study, 4T1 tumor-bearing micewere injected with HMSN(DOX)-TRC105 (targeted group: 10 mg HMSN/kg, 6.5 mg DOX/kg), and HMSN(DOX) (non-targeted group: 10 mg HMSN/kg, 6.5 mg DOX/kg). The mice were then sacrificed at 0.5 h p.i. for ex vivo optical imaging in the IVIS system (Ex = 465 nm, Em = 580 nm).
