Abstract

Suzaku observed the region including HESS J1809–193, a TeV unidentified source, and confirmed the existence of extended hard X-ray emission previously reported by ASCA, as well as hard X-ray emission from PSR J1809–1917 in this region. A one-dimensional profile of the diffuse emission is represented along with a Gaussian model with a best-fit σ of 7 ± 1. The diffuse emission extends for at least 21 pc (at the 3σ level, assuming a distance of 3.5 kpc), and has a hard spectrum with a photon index of Γ ≈ 1.7. The hard spectrum suggests a pulsar wind nebula origin, which is also strengthened by the hard X-ray emission from PSR J1809–1917, itself. Thanks to the low background of Suzaku XIS, we were able to investigate the spatial variation of the energy spectrum, but no systematic spectral change in the extended emission was found. These results imply that the X-ray emitting pulsar wind electrons can travel up to 21 pc from the pulsar without any noticeable energy loss via synchrotron emission.

Key words: gamma rays: observations — ISM: individual (HESS J1809–193) — stars: pulsars: individual (PSR J1809–1917) — X-rays: ISM

1. Introduction

A galactic plane survey with the H.E.S.S. Cherenkov telescope system revealed dozens of the new very-high-energy (VHE) γ-ray sources (Aharonian et al. 2005a, 2006a). Many of them have no counterparts in other wavelengths, and are thus called “unidentified (unID) TeV sources”. Today, about 40 such unID TeV sources are known on the galactic plane. Most of them are located within a height of ±1° from the galactic plane, and are intrinsically extended. Despite a large number of intensive studies during the last several years, their origin is unclear (Hinton 2007).

X-ray follow-up observations of the unID TeV sources are now on-going. Although supernova remnants (SNRs) or hypernova remnants were suggested to be major counterpart candidates of these TeV unID sources (Yamazaki et al. 2006; Ioka & Meszaros 2010), only a few of them have actually been identified as SNRs (Nakamura et al. 2009; Aharonian et al. 2008). On the other hand, rather surprisingly, several unID TeV sources have been identified as pulsar wind nebulae (PWNe) (Anada et al. 2009; Uchiyama et al. 2009, for example). They seem to be rather old, previously unknown PWNe, compared to the PWNe already identified and well studied in X-rays.

The first H.E.S.S. observations of the region around PSR J1809–1917 were made from 2004 May through June as part of a systematic survey of the inner Galaxy (Aharonian et al. 2005a, 2006a). Because marginal VHE γ-ray signals were detected, HESS J1809–193 was observed again in 2004 and 2005, and significant γ-ray emission was confirmed (Aharonian et al. 2007). A recent study of this source by H.E.S.S. was reported by Renaud et al. (2008). Fitting the excess map with a 2-D symmetric Gaussian, the best-fit position and intrinsic source extension (in r.m.s.) were determined as being (RA, Dec) = (18°09′52″, −19°23′42″) and 0′25 ± 0′02, respectively.

PSR J1809–1917 is a radio pulsar discovered by the Parkes Multi-beam Pulsar Survey (Morris et al. 2002). It is located at the position (RA, Dec) = (18°09′43″, −19°17′38″) with a period of P = 82.7 ms and a period derivative of ĎP = 2.55 × 10−14 ss−1. The distance to the source was estimated to be d = 3.5 kpc from the pulsar’s dispersion measure using the NE2001 galactic electron-density model (Cordes & Lazio 2002). The characteristic age and the spin-down luminosity are τc = 51 kyr and ĎE = 1.8 × 1036 erg s−1, respectively.

A γ-ray spectral analysis performed by Komissar et al. (2008) indicated that the spectral slope is different between the regions near the pulsar and far away. This is the second case that the spatial variation of the spectral slope has been revealed in VHE γ-ray emission. The first case was HESS J1825–137 (Aharonian et al. 2006b), which is largely extended in both the VHE γ-ray and X-ray bands (Uchiyama et al. 2009).

An ASCA observation revealed diffuse, non-thermal emission in the vicinity of PSR J1809–1917 (Bamba et al. 2003a). Kargaltsev and Pavlov (2007) detected a bright point X-ray source that was positionally consistent with the PSR J1809–1917, and resolved a surrounding compact PWN utilizing the very high angular resolution of Chandra. The PWN has a “head-tail” profile, consisting of a southern-head, which is coincident to the pulsar, and a northern-tail. Kargaltsev and Pavlov (2007) claimed that this cometary morphology can be attributed to a bow shock created by the pulsar moving supersonically to the southern direction. However, it is still unknown whether the faint diffuse emission discovered by ASCA is related to the PWN or not. In this paper, we present a detailed analysis of the diffuse emission for the first time using Suzaku. Suzaku, characterized by a low

Fig. 1. Smoothed excess map measured by H.E.S.S. around HESS J1809–193 (Aharonian et al. 2007). The position of the PSR J1809–1917 is marked with a cyan cross, whose Chandra image (Kargaltsev & Pavlov 2007) is shown in the inset at the top right of the figure. The best-fit position and the extent of the γ-ray source are marked with a black cross and a dashed circle, respectively. Two cyan squares indicate the two XIS field of views (FOVs) during the Suzaku observations, which are referred to as the North and the South pointing, respectively.

detector background compared to Chandra and XMM-Newton, is very suitable for the analysis of faint and diffuse X-ray emission, such as HESS 1809–193.

2. Observations

We observed HESS J1809–193 with Suzaku (Mitsuda et al. 2007) in 2008 April. Suzaku is equipped with two types of instruments: the X-ray Imaging Spectrometers (XIS: Koyama et al. 2007) at the foci of four X-Ray Telescopes (XRT: Serlemitsos et al. 2007) and the Hard X-ray Detector (HXD: Takahashi et al. 2007; Kokubun et al. 2007). The observation was carried out with two pointings at north and south of the source region (figure 1) in order to cover the pulsar and extended VHE γ-ray emission along the direction of the elongated shape of the PWN (Kargaltsev & Pavlov 2007). Three XISs (XIS 0, 1, 3) out of four were operated in the normal clocking mode with Spaced-row Charge Injection (SCI) (Nakajima et al. 2008). We analyzed the data processed by the version 2.2 pipeline. We are interested in the spatial variations of a scale of arcminutes. Hence, we concentrated on an analysis of the XIS data in the present work, since the HXD does not have a spatial resolution within a field of view of ~30′ (FWHM). We applied the standard screening criteria to the XIS data¹ to obtain cleaned event lists. After data screening, the net exposures were 51.5 ks and 44.2 ks for the north and south pointings of XIS, respectively. The Suzaku observation log and exposures are summarized in table 1. We used the HEADAS version 6.5 software package for data analysis.

3. Results

3.1. X-Ray Image

In order to make images of this field, we corrected the vignetting effect by dividing the image by a flat sky image simulated using xissim (Ishisaki et al. 2007) after subtracting non–X-ray background (Tawa et al. 2008). In this simulation, we assumed the input energy spectrum as that extracted from the red rectangular region (see subsection 3.2). Hereafter, all images are vignetting corrected. Figure 2 shows a Suzaku XIS 2–10 keV image of the HESS J1809–193 region.

We confirmed largely extended emission reported by ASCA (Bamba et al. 2003a). In addition, we found that the extended emission has several peaks. The pulsar is the brightest in the FOV, and the western edge of the FOV is also significantly bright, which was already hinted by ASCA (Bamba et al. 2003a).

We determined the extension of the diffuse emission as follows: We created a 1-dimensional profile of the surface brightness from the rectangular region shown in figure 2 (left), which runs from north to south. We selected the direction that would enable us to create the longest profile. We did not take a symmetric region around the pulsar, because the faint and diffuse emission is significantly asymmetric. Although there is a point source south of the pulsar at (272.42, −19.43), its flux in the integrated region is only 1% of the central pulsar, and is thus negligible. The thus-created 1-dimensional profile is shown in figure 2 (right). Note that the surface brightness was normalized to the peak brightness. We fitted the profile with a Gaussian function plus a constant to evaluate its extension. In the fitting, we ignored the brightest part around the pulsar with a width of 2′9 (corresponding to the point-spread function

Fig. 2. Left: Suzaku XIS image of the region including HESS J1809–193. The pseudo-color represents vignetting-corrected, log-scaled intensity levels in the 2.0–10.0 keV band. The yellow cross indicates the centroid of HESS J1809–193, and the yellow lines represent 80%, 60%, and 40% contours of the peak of the VHE γ-ray (Renaud et al. 2008). Right: normalized 1-dimensional profile of the surface brightness in the 2.0–10.0 keV band along the direction from north to south in the green rectangle indicated with a spatial bin size of 1.0. Solid curve and horizontal dashed line show the best-fit Gaussian profile and a constant, respectively. The bright peak corresponding to the pulsar was ignored in this fit (2.9 wide, inner part between the two vertical dashed lines).

Fig. 3. Left: NXB-subtracted XIS spectrum in the 4.0–7.2 keV band extracted from the region enclosed with a red rectangle in figure 2 (left). The best-fit model, an absorbed power-law with three iron lines, is also shown by a solid line (each component in a dot-dashed line). The bottom panel shows residuals to the best-fit model. Right: same as the left one, but in the 2.0–7.2 keV band. Narrow Gaussian lines were added to the model below 4 keV.

of the XRT). Consequently, we found that the diffuse emission extends up to ~20′ away from the pulsar. The Gaussian center was found to be offset by ~3′ from the pulsar and the rms width to be σ = 7′ ± 1′.

3.2. Energy Spectra

We studied the spatial variation of the X-ray energy spectra of the diffuse emission. We generated a detector response file and an auxiliary response file using xisrmfgen, and xissimarfgen (Ishisaki et al. 2007) and performed model fitting using XSPEC version 12.4.0.

First we examined the energy spectrum from an outskirt of the H.E.S.S. source region (the red rectangular region in figure 2) in order to estimate the contribution of the Galactic Ridge X-ray Emission (GRXE) on this particular area. The bright source at the south-east corner (circled in red) was excluded in this analysis. We subtracted the non-X-ray background (NXB) estimated using xisnxbgen (detail of the method described in Tawa et al. 2008), and averaged all of the available XISs (XIS 0, 1, 3) data. Because the NXB becomes high above 7.2 keV (in particular for XIS 1, which has a back-illuminated chip), we used data only below 7.2 keV. We fitted the spectra in 4.0–7.2 keV and 2.0–4.0 keV separately following a reproduction procedure of GRXE in Ebisawa et al. (2008). The model adopted is a power-law plus three narrow Gaussian (intrinsic width fixed to zero) in 4.0–7.2 keV, or four Gaussian lines in 2.0–4.0 keV. The spectra and the best-fit models are shown in figure 3. The equivalent widths of the
Table 2. Iron lines in the background region compared with values of the GRXE.

† Center energies and equivalent widths determined by the GRXE observation with Suzaku by Ebisawa et al. (2008).

Fig. 4. Left: Suzaku XIS image of the north pointing in the 2.0–10.0 keV band and designation of the 16 sub-regions for spectral variation study. Right: Correction factors for each region, which take account of the vignetting effects, differences of the exposure, and the extraction area between the source region and the GRXE region (the red rectangle in figure 2).

Iron lines are summarized in Table 2. These equivalent widths are comparable to those of GRXE described in Ebisawa et al. (2008). We thus conclude that the X-ray emission in this region can be regarded as pure GRXE, and that no significant contribution from the pulsar is present.

In the next step, we divided the sky region of the north pointing into a “check pattern”, as shown in Figure 4 (left), in order to find any possible spatial variations of the spectral slope. Here, we refer to these regions as the number indicated in Figure 4 (left) with the prefix “Grid” (Grid 1, Grid 2, ...). We used a two-component model for the fit: an absorbed power-law plus the GRXE. We used the model GRXE spectrum (as explained below) to subtract the diffuse background.

The model GRXE spectrum was constructed as follows. The background spectrum was fitted in the 2.0–7.2 keV band with a model of an absorbed power-law plus 7 narrow Gaussians, as explained above. The absorption column density was fixed to $1.0 \times 10^{22}$ cm$^{-2}$. The best-fit parameters, besides the iron line parameters given in Table 2, are listed in Table 3.

Normalization for each extraction region was adjusted while taking account of differences in the vignetting effects, size of the extraction region, and exposure time between the north and south pointings. The correction factors of the vignetting effect (shown in Figure 4 right) were determined by simulation. We subtracted the non-X-ray background (NXB) estimated by using xisnxbgen. Figure 5 shows the XIS spectra (averaged for XISs 0, 1, and 3) and the best-fit models for all of the 16 regions in the 2.0–10 keV band. Because Grids 1, 4, 13 were illuminated with the calibration sources, the data between 5.73–6.67 keV were removed from the fit. The fit results are summarized in Table 4. The spatial distribution of the spectral indices is shown in Figure 6. In order to make the statistics better, we also fit the combined spectra of Grids 6 and 7 (for the region close to the emission peak) and Grids 11, 14, and 15 (for the region far from the emission peak). The results are included in Table 4. From these analyses, we concluded that there is no systematic trend of the spatial variations in the spectral index in this field of view.
Table 3. Best-fit parameters of an absorbed power-law model with emission lines.

| Model component | Parameter | Value* |
|-----------------|-----------|--------|
| Continuum       | $N_H$ ($10^{22}$ cm$^{-2}$) | 1.0 (fixed) |
|                 | $\Gamma$ | $1.40 \pm 0.06$ |
| Emission lines  | Energy (keV) | S XV $2.43 \pm 0.02$ |
|                 |           | S XVI $2.61 \pm 0.04$ |
|                 |           | Ar XVII $3.13 \pm 0.02$ |

4. Discussion

Using Suzaku, we have clearly shown the presence of large-scale diffuse emission around HESS J1809−193, which was already suggested by ASCA (Bamba et al. 2003a). The extension of the diffuse emission is at least $\sim 21'$ (3$\sigma$ of the Gaussian approximation). The diffuse spectrum has a photon index of $\Gamma \sim 1.7$, which is much harder than those of SNRs with synchrotron X-ray emitting shells ($\Gamma \sim 2$–3), such as SN 1006, RX J1713−3946, and others (Bamba et al. 2008; Takahashi et al. 2008, for example). Such a hard spectrum, on the other hand, reminds us of the PWN origin (Kargaltsev & Pavlov 2008). This hypothesis is, in fact, strengthened by the very existence of the PSR J1809−1917.

The TeV emission may also have a PWN origin, because it positionally coincides with the region including the pulsar...

Fig. 6. Spatial distribution of the spectral indices around PSR J1809–1917. Left: best-fit photon index map. The gray scale indicates the photon indices; light gray means the spectrum is hard while dark gray means soft. Right: photon indices of each grid with 90% error bars.
and the diffuse X-ray emission, although the center of the TeV emission is offset by ~6′ (a projected distance of 6 pc at 3.5 kpc) from the pulsar. If both the TeV and X-ray emissions are from the same PWN, their origin is accelerated electrons via inverse Compton (TeV) and synchrotron mechanisms (X-rays). Typical energies of responsible electrons are ~20 TeV for the TeV emission and ~80 TeV for X-rays, respectively. The former has much longer synchrotron life timescales than the latter (Mattana et al. 2009, for example). If we assume that the electrons that emit TeV gamma-rays have the same age as the pulsar (τ = 51 kyr), and those for the X-rays are very fresh, the positional offset may be explained by the proper motion of the pulsar. To explain the offset of ~6′, the transverse velocity of the pulsar needs to be ~120 km s⁻¹, which can be explained with the average transverse velocity of radio pulsars (Lyne & Lorimer 1994, ~300 km s⁻¹). On the other hand, the tails seen in the Chandra image (if it is indeed a tail not a jet) suggest that the pulsar is moving southward and its velocity vector is at an angle of ~190°–200° East of North (Kargaltsev & Pavlov 2007). Now, if we assume that the pulsar was born at the center of the TeV source and moved to its current position, its velocity vector would have to be at an angle of 10°–20° West of North. Therefore, the angle between these two velocity vectors will be ~140°–160°, which makes this scenario unlikely. Another possible scenario to make such an offset is collision between the reverse shock and the PWN (Pavlov et al. 2008), like the case for Vela X (Blondin et al. 2001; Gaensler et al. 2003).

In the young PWNe, it is suggested that the X-ray spectra become softer with the distance from the pulsars due to synchrotron energy loss of the accelerated electrons (Mori et al. 2004, for example). However, we could not find any hint of such softening (figure 6). This means that electrons do not lose significant energies via synchrotron emission. The X-ray size of HESS J1809–193 is ~21′ (= 3σ), or 21 pc with an assumed distance of 3.5 kpc. The synchrotron lifetime of accelerated electrons (τ_{syn}) is τ_{syn} = 6.8 kyr (B/3 μG)^{-3/2} (E_{syn}/2 keV)^{-1/2}, where B and E_{syn} are the magnetic field and the mean energy of synchrotron emission from accelerated electrons, respectively. In order to explain the size of the X-ray diffuse emission, the transport velocity of accelerated electrons should be higher than 21 pc/τ_{syn} ~ 3.0 × 10^3 km s⁻¹ (B/3 μG)^{3/2} (E_{syn}/2 keV)^{1/2}, which seems to be very fast for an old PWN, and even comparable to the forward shock velocities of young SNRs. It is known that the diffusion coefficient in young PWNe and SNRs is too small to diffuse out to such a large scale, when the magnetic field is turbulent (Shibata et al. 2003; Bamba et al. 2003b, 2005, for example). Therefore, the current observation suggests that the turbulence of magnetic fields in old PWN systems are smaller than those in young systems. If the turbulence of the magnetic fields in old PWN systems is smaller than that in young systems, such a fast diffusion may be explained, although we have no such model for old PWNe. In supernova remnants, we have some indication that the turbulence becomes smaller when the SNR becomes older (Bamba et al. 2005), and similar mechanism might work for PWNe.

We have a similar case, HESS J1825–137, which is another unID TeV source with a possible PWN origin. Uchiyama et al. (2009) found that the X-ray photon index is nearly constant over the emission region, which may suggest that HESS J1825–137 also might have small turbulence of the magnetic field. Therefore, we suppose fast transportations of accelerated electrons may be rather common phenomena in old PWNe. Further, similar samples of unID TeV sources may confirm this hypothesis.

### 5. Summary

- We observed the TeV PWN candidate HESS J1809–193 with Suzaku, and confirmed an extended emission around the PSR J1809–1917. The size of the X-ray emission is at least ~21′, or 21 pc at 3.5 kpc.
- The extended emission has a very hard nonthermal spectrum with a photon index of ~1.7. No systematic spatial variation of the photon index has been found, which implies that accelerated electrons do not lose their energy when they run from the pulsar to the edge of the emission region. We have to consider very fast diffusion in an old PWN to reproduce such phenomena. If the turbulence of the magnetic fields in old PWN systems is smaller than that in young systems, such fast diffusion may be explained.

We would like to thank an anonymous referee for useful comments and suggestions. We acknowledge all of the Suzaku team members for their gracious support. The authors also thank K. Mori and R. Yamazaki for fruitful comments. A. Bamba is supported by JSPS Research Fellowship for Young Scientists (19-1804).
