ABSTRACT

We study the evolution of the energy spectrum of cosmic-ray electrons accelerated at spherically expanding shocks with low Mach numbers and the ensuing spectral signatures imprinted in radio synchrotron emission. Time-dependent simulations of diffusive shock acceleration (DSA) of electrons in the test-particle limit have been performed for spherical shocks with the parameters relevant for typical shocks in the intracluster medium. The electron and radiation spectra at the shock location can be described properly by the test-particle DSA predictions with the instantaneous shock parameters. However, the volume integrated spectra of both electrons and radiation deviate significantly from the test-particle power-laws, because the shock compression ratio and the flux of injected electrons at the shock gradually decrease as the shock slows down in time. So one needs to be cautious about interpreting observed radio spectra of evolving shocks by simple DSA models in the test-particle regime.

Key words : acceleration of particles — cosmic rays — galaxies: clusters: general — shock waves

1. INTRODUCTION

X-ray emitting baryonic gas in galaxy clusters is thought to be heated via collisionless shocks that are induced during the formation of the large scale structure in the Universe (e.g. Ryu et al. 2003; Kang et al. 2007; Vazza et al. 2009; Skillman et al. 2011). The gas infalling toward nonlinear structures go through strong accretion shocks first, and later may encounter much weaker shocks produced by mergers and chaotic flow motions inside the hot intracluster medium (ICM) (Ryu et al. 2003). In fact, about a dozen of these weak ICM shocks have been detected through X-ray observations as bow shocks associated with merging activities (e.g. the so-called bullet cluster 1E 06576, Markevitch et al. 2002; Akamatsu & Kawahara 2013; Ogrean & Brüggen 2013).

In addition, quiet a few ICM shocks have been identified as “radio relic shocks” in the outskirts of galaxy clusters through radio synchrotron radiation from cosmic-ray (CR) electrons that are thought to be accelerated via diffusive shock acceleration (DSA) (van Weeren et al. 2010, 2011; Nuza et al. 2012). Radio relics are interpreted as synchrotron emitting structures that contain relativistic electrons of the Lorentz factor $\gamma_e \sim 10^4$ gyrating in the mean magnetic fields of $B \sim 5-7 \mu G$ in the ICM (Kang et al. 2012; Feretti et al. 2012; Pinzke et al. 2013; Brunetti & Jones 2014). The electrons are expected to be accelerated at weak shocks with the sonic Mach number, $M_s \sim 2-4$, inferred from the spectral index of synchrotron emission immediately behind the shock, $\alpha_\nu > 0.6$. Note that the spectral index of the volume-integrated synchrotron radiation is normally $A_\nu = \alpha_\nu + 0.5$, since electrons cool via synchrotron and inverse-Compton (iC) losses behind the shock (e.g. Kang 2011).

It is well accepted that the DSA theory can explain how nonthermal particles are produced through their interactions with MHD waves in the converging flows across astrophysical shocks (Bell 1978; Drury 1983; Malkov & Drury 2001). In the test particle limit where the CR pressure is dynamically insignificant, it predicts that the CR energy spectrum at the shock position has a power-law energy spectrum, $N(E) \propto E^{-\gamma}$, where $r = (\sigma + 2)/(\sigma - 1)$ and $\sigma = \rho_2/\rho_1$ is the shock compression ratio. (Hereafter, we use the subscripts ‘1’ and ‘2’ to denote the conditions upstream and downstream of shock, respectively.) Hence the DSA theory can provide the most simplistic and natural explanation for the spatially resolve synchrotron radiation spectrum at the shock location, $j_\nu(x_s) \propto \nu^{-\alpha_\nu}$, where $\alpha_\nu = (r - 1)/2$.

On the other hand, pre-acceleration of thermal electrons to suprathermal energies and the subsequent injection into the DSA process still remains very uncertain, especially at low Mach number shocks in high beta ($\beta = P_B/P_E$) plasmas (e.g. Kang et al. 2014). Recently, there have been some efforts to understand complex plasma instabilities and wave-particle interactions, operating at nonrelativistic shocks with the parameters relevant for weak cluster shocks, through Particle-in-Cell (PIC) and hybrid plasma simulations (e.g., Riquelme & Spitkovsky 2011; Caprioli & Spitkovsky 2014a,b; Guo et al. 2014). They have demonstrated that the self-excitation of MHD/plasma waves via various instabilities, such as Bell’s resonant and nonres-
onant instabilities and firehose instability, are crucial in the injection process. Moreover, it has been shown that protons can be injected efficiently at quasi-parallel shocks, while the electron injection occurs preferentially at quasi-perpendicular shocks. Here, we adopt a phenomenological injection model in which suprathermal electrons with the momentum $p > p_{\text{inj}}$ are allowed to cross the shock transition and participate in the Fermi 1st-order acceleration, where the injection momentum, $p_{\text{inj}}$, is several times the peak momentum of the postshock thermal protons (Kang et al. 2002). This subject will be discussed in details in Section 2.2 below.

The morphology of observed radio relics varies rather widely from diffuse patches to well-defined, thin elongated structures. For example, the so-called Sausage relic in CIZA J2242.8+5301 is located at a distance of $\sim 1.5$ Mpc from the cluster center and has an arc-like shape of $\sim 55$ kpc in width and $\sim 1$–2 Mpc in length (van Weeren et al. 2010). So it would be natural to assume, at least for the cases similar to the Sausage relic, that radio relics consist of some portions of a spherical shell of radiating electrons projected onto the sky plane. The physical width of this shell is mainly determined by the cooling length of electrons, $\Delta l \sim t_{\text{rad}}(\gamma_e)u_2$, where $u_2$ is the flow speed behind the shock. But the projection of a partial shell could involve some geometrical complexities such as the extension of the partial shell and the viewing angle (e.g. van Weeren et al. 2010, 2011; Kang et al. 2012).

For several observed radio relics the projected spatial profiles of the radio flux, $S_{\nu}(r)$, and the spectral index, $\alpha_{\nu}(r)$, have been explained by the electron energy spectrum $N_e(\gamma_e, r)$ behind one-dimensional planar shocks (e.g. van Weeren et al. 2010, 2011; Kang et al. 2012). This can be justified, since the width ($\sim 50$–100kpc) of those relics is much smaller than their length ($\sim 1$–2 Mpc). Note that a simple projection of a spherical shell on the sky plane was attempted in these previous papers, although the DSA simulation results for a planar shock was adopted for $N_e(\gamma_e, r)$.

In this paper we consider the electron acceleration at spherical shocks with $M_s \sim 2.5$–4.5, which expand into a hot uniform ICM. A self-similar solution, because the sonic Mach numbers of our model shocks are not large enough. Nevertheless, the shock slows down approximately as $u_s(t) \propto t^{-3/5}$. This model may represent a spherically decelerating shock, but it is not intended to mimic realistic cluster shocks by no means. Note that the flow speed, $u(r, t)$, is only dynamical information that is fed into the diffusion-convection equation for the evolution of the electron distribution function, $f_e(r, p, t)$. As the shock slows down and weakens, the shock compression ratio and the injection flux of CR electrons should decrease in time. Consequently, the amplitude of electron spectrum at the injection momentum reduces and the electron energy spectrum steepens gradually.

Considering that the synchrotron/iC cooling time scale ($t_{\text{rad}} \sim 10^8$ yr) for the electrons of our interest ($\gamma_e \sim 10^4$) is shorter than the dynamical time scale of typical cluster shocks ($t_{\text{dyn}} \sim 10^9$ yr), the electron energy spectrum at the shock location is expected to follow the test-particle DSA predictions with the instantaneous shock parameters. But the spatial profile of the electron distribution function, $f_e(r, p)$, and the volume-integrated distribution function, $F_e(p) = \int 4\pi f_e(r, p) r^2 dr$, would be affected by the time-dependent evolution of the spherically decelerating shock. Our primary objective here is to study any signatures of such time-dependence via DSA simulations of a heuristic example, i.e., a spherical blast wave.

In the next section we describe the numerical method and some basic physics of the DSA theory. The simulation results of a planar shock and a spherical shock will be compared, and spherical shocks with different magnetic field models will be discussed in Section 3. A brief summary will be given in Section 4.

## 2. DSA NUMERICAL SIMULATIONS

### 2.1 1D Spherical CRASH Code

We consider DSA of CR electrons at nonrelativistic, gasdynamical shocks in one-dimensional (1D) spherical geometry. So we solve the following time-dependent diffusion-convection equation for the pitch-angle-averaged phase space distribution function for CR electrons, $g_e(r, p, t) = f_e(r, p, t)/[^4]$

$$\frac{\partial g_e}{\partial t} + u \frac{\partial g_e}{\partial r} = \frac{1}{3r^2} \frac{\partial}{\partial r} \left[ r^2 (D(r, y) \frac{\partial g_e}{\partial y}) \right] + p \frac{\partial}{\partial y} \left( \frac{b}{p^2} g_e \right),$$  \tag{1}$$

where $u(r, t)$ is the flow velocity, $y = \ln(p)$ and $D(r, p)$ is the spatial diffusion coefficient (Skilling 1975). For $D(r, p)$, we adopt a Bohm-like diffusion coefficient with weaker non-relativistic momentum dependence

$$D(r, p) = 1.7 \times 10^{19} \mathrm{cm}^2 \mathrm{s}^{-1} \left( \frac{B(r)}{1 \mu \mathrm{G}} \right)^{-1} \left( \frac{p}{m_e c} \right).$$  \tag{2}$$

The cooling term $b(p) = -dp/dt$ accounts for electron synchrotron and iC losses:

$$\left( \frac{1}{t_{\text{rad}}(\gamma_e)} \right) = \frac{b(p)}{p} = \frac{4e^4}{9m_e^2 c^5} B_e^2 \cdot \gamma_e \tag{3}$$

in cgs units, where $e$ and $m_e$ are electron charge and mass, respectively. The 'effective' magnetic field strength $B_e$ is $B^2 + B_{\text{rad}}^2$ takes account for radiative
losses due to both synchrotron and iC processes, where $B_{\text{rad}} = 3.24 \mu G(1+z)^2$ corresponds to the cosmic background radiation (CBR) at redshift $z$ (Schlickeiser 2002). In this study, we set $z = 0.2$ as a reference epoch and so $B_{\text{rad}} = 4.7 \mu G$. Then the cooling time scale for electrons is given as

$$t_{\text{rad}}(\gamma_e) = 3.8 \times 10^7 \text{ yr} \left( \frac{B_e}{8 \mu G} \right)^{-2} \left( \frac{\gamma_e}{10^4} \right)^{-1}. \quad (4)$$

For typical ICM conditions relevant for radio relics (i.e. $n_H \sim 10^{-4} \text{ cm}^{-3}$ and $B \sim 1 \mu G$), the Coulomb loss dominates over the other losses for relativistic electrons with $\gamma_e \lesssim 100$, while the synchrotron and iC losses are the main cooling processes for $\gamma_e \gtrsim 100$ (Sarazin 1999). Nonthermal bremsstrahlung loss is much less important and can be ignored for relativistic electrons, since its cooling time scale is longer than the Hubble time (Petrosian 2001).

Since we focus on the synchrotron emission from CR electrons here, we do not need to consider the acceleration of CR protons. Moreover, the CR proton pressure is expected to be dynamically insignificant at weak shocks with $M_s \lesssim 5$, so we can just follow the hydrodynamic evolution of the shock without following DSA of CR protons. This alleviates significantly the extreme requirements for computational resources, since much wider ranges of particle energy and diffusion length/time scales should be included, if both proton and electron populations were to be calculated. For instance, the maximum energy of electrons are limited to $\sim 100 \text{ TeV}$ for the problem considered here, while that of protons can go up much higher energies by several orders of magnitude.

At weak shocks in the test-particle limit, the CR feedback becomes negligible and the background flow, $u(r,t)$, is governed by the usual gasdynamic conservation in 1D spherical coordinates (Kang & Jones 2006):

$$\frac{\partial P}{\partial t} + \frac{\partial}{\partial r}(P u) = -\frac{2}{r} P u, \quad (5)$$

$$\frac{\partial (P u)}{\partial t} + \frac{\partial}{\partial r}(P u^2 + P) = -\frac{2}{r} P u^2, \quad (6)$$

$$\frac{\partial (\rho e_g)}{\partial t} + \frac{\partial}{\partial r}(\rho e_g u + P u) = -\frac{2}{r} (\rho e_g u + P u), \quad (7)$$

where $P$ is the gas pressure, $e_g = P/(\rho(\gamma_g - 1)) + u^2/2$ is the total energy of the gas per unit mass and the rest of variables have their usual meanings. The gas adiabatic index is assumed to be $\gamma_g = 5/3$, since the background gas flow is nonrelativistic.

In order to optimize the shock tracking scheme, a comoving frame that expands with the instantaneous shock speed is adopted. In such a frame, a spherically expanding shock can be made to be stationary by adopting comoving variables which factor out a uniform expansion. The details of the CRASH (Cosmic-Ray Amr SHock) code in a comoving spherical grid can be found in Kang & Jones (2006).

### 2.2 Electron Pre-heating and Injection

Injection of suprathermal particles into the Fermi process remains to be one of the outstanding problems in the DSA theory. In the so-called thermal leakage injection model, suprathermal particles with $p \gtrsim p_{\text{inj}} \sim 3p_{\text{th},p}$ are expected to re-cross to the shock upstream and participate in the DSA process, because the shock thickness is of the order of the gyroradius of postshock thermal protons (e.g. Kang et al. 2002). Here, $p_{\text{th},p} = \sqrt{2m_e k_B T_2}$ is the most probable momentum of thermal protons with postshock temperature $T_2$ and $k_B$ is the Boltzmann constant. On the other hand, recent hybrid and PIC simulations of collisionless shocks have revealed a somewhat different picture, in which incoming protons and electrons are specularly reflected at the shock surface and scattered by plasma waves excited in the foreshock region, leading to suprathermal populations (e.g. Guo & Giacalone 2013; Guo et al. 2014; Caprioli et al. 2014). The trajectories of these suprathermal particles are non-diffusive and confined to the region mostly upstream of the shock transition.

If one assumes that downstream electrons and protons have Maxwellian distributions defined with the same kinetic temperature, $T_e \approx T_p$, then thermal electrons have much higher speeds but much smaller momenta compared to thermal protons (i.e., $p_{\text{th},e} = (m_e/m_p)^{1/2} p_{\text{th},p}$). So electrons must be pre-accelerated from their thermal momenta to $p_{\text{inj}} \sim 3p_{\text{th},p} \sim 130p_{\text{th},e}$, before they can begin to take part in the DSA process. In fact, pre-heating of electrons above the thermal distribution have been widely observed in space and laboratory plasmas (e.g. Vasyliunas 1968). Such suprathermal non-Maxwellian distributions can be described by the combination of a Maxwellian-like core and a power-law tail, which is known as the $\kappa$-distribution:

$$f_\kappa(p) = \frac{\sqrt{2}}{\pi^{1.5}} \frac{p^{-3}}{\rho_\text{th}^2} \frac{\Gamma(\kappa + 1)}{\Gamma(\kappa - 1/2)} \left[ 1 + \left( \frac{p^2}{(\kappa - 3/2)p_{\text{th}}^2} \right)^{-(\kappa+1)} \right]^{-1}, \quad (8)$$

where $p_{\text{th}} = \sqrt{2m_k k_B T_2}$ is the thermal peak momentum, the mass of the particle is $m = m_e$ for electrons and $m = m_p$ for protons, and $\Gamma(x)$ is the Gamma function (e.g. Pierrard & Lazar 2010). In the limit of large $\kappa$, it asymptotes to the Maxwellian distribution.

The power-law index of the $\kappa$-distributions for electrons and protons, $\kappa_e$ and $\kappa_p$, respectively, should depend on plasma and shock parameters, i.e., $\beta$, $M_s$, $M_A = u_s/u_A$ (where $u_A = B/\sqrt{4\pi \rho}$ is the Alfvén speed), and the shock obliquity angle, $\Theta_{\text{Bn}}$. For example, the electron distributions measured near interplanetary shocks can be fitted with the $\kappa$-distributions with $\kappa_e \sim 2-5$, while the proton distributions prefer a somewhat larger $\kappa_p \gtrsim 10$ (e.g. Pierrard & Lazar 2010).

As an illustration, Fig. 1 compares the electron $\kappa$-
Fig. 1.— Schematic model demonstrating the pre-heated suprathermal distributions and the power-law distributions of electrons accelerated at a weak shock of $u_s = 3.2 \times 10^3$ km s$^{-1}$ and $M_s = 3$. The Maxwellian distribution (black solid line) and $\kappa$-distributions with $\kappa_e = 1.6$ (red dotted), 2.0 (blue dashed), 2.5 (green dot-dashed), and 3.0 (magenta dot-long dashed) are shown for electrons. For protons only the Maxwellian distribution (black dot-long dashed line) is shown. The vertical line demarcates the injection momentum, so $f_e(p) = f_{e,\kappa}(p/p_{\text{inj}})$ for $p < p_{\text{inj}}$ and $f_e(p) = f_{e,\kappa}(p_{\text{inj}}) \cdot (p/p_{\text{inj}})^{-q}$ for $p \geq p_{\text{inj}}$. The filled circle marks the amplitude of $f_{p,M}(p_{\text{inj}})$ at the injection boundary for the proton Maxwellian distribution. The distributions, $f_{e,\kappa}(p)$ with $\kappa_e = 1.6 - 3.0$ for $p \leq p_{\text{inj}}$ and the electron power-law distribution, $f_{e,\kappa}(p_{\text{inj}}) \cdot (p/p_{\text{inj}})^{-q}$ for $p > p_{\text{inj}}$. Here the adopted shock parameters are $u_s = 3.2 \times 10^3$ km s$^{-1}$, $M_s = 3$, and the DSA power-law slope, $q = 3$. The Maxwellian distributions for electrons and protons are also plotted for comparison. These $\kappa$-distributions may represent the pre-heated electron populations, while the power-law distributions may represent the shock accelerated electron populations. We note that pre-heated electrons are assumed to injected at $p = p_{\text{inj}}$ with the amplitude, $f_{e,\kappa}(p_{\text{inj}})$, which is much larger than the corresponding value for the electron Maxwellian distribution, $f_{e,M}(p_{\text{inj}})$. Here we adopt $p_{\text{inj}} \approx 5.3 m_p u_s$, which becomes $p_{\text{inj}} \approx 3.3 p_{\text{th}}$, for $M_s = 3$. The filled circle on the proton Maxwellian distribution marks the amplitude of proton distribution, $f_{p,M}(p_{\text{inj}})$, at the injection momentum, which is larger than $f_{e,\kappa}(p_{\text{inj}})$ by several orders of magnitude.

For the case shown in Fig. 1, the ratio of CR electron to proton numbers can be approximated by

$$K_{e/p} \approx f_{e,\kappa}(p_{\text{inj}})/f_{p,M}(p_{\text{inj}}),$$

which becomes $K_{e/p} \sim 1/300$ for $\kappa_e = 1.6$. So Fig. 1 demonstrates that the ratio becomes $K_{e/p} \sim 10^{-3} - 10^{-2}$, depending on the value of $p_{\text{inj}}$, if the electrons are pre-accelerated to $\kappa$-distributions with $\kappa_e \lesssim 2$.

Since the main goal of this study is to explore how the electron energy spectrum and the synchrotron emission are affected by the dynamical evolution of spherically expanding shocks (i.e. $u_s(t)$ and $r_s(t)$), here it is not important to know the amplitudes of $f_{e,\kappa}(p_{\text{inj}})$ for a given set of models parameters (i.e. $\kappa_e$ and $p_{\text{inj}}/p_{\text{p,th}}$). So we simply assume that the injection momentum decreases with the shock speed as $p_{\text{inj}}(t) \approx 5.34 m_p u_s(t)/\sigma$, and the electrons are injected with the value $K_{e/p} = 1$ in the simulations described below. Note that here we do not attempt to compare theoretically estimated radio flux, $S_\nu$, with observed radio flux of any specific radio relics.
2.3 Shock Accelerated CR Electron Spectrum

In the test-particle regime of DSA, the distribution of CR distribution function at the shock position can be approximated, once it reaches equilibrium, by a power-law spectrum with super-exponential cutoff,

\[ f_{e,2}(p) \approx f_{\text{inj}} \cdot \left( \frac{p}{p_{\text{inj}}} \right)^{-q} \exp \left( -\frac{p_e^2}{p_{\text{eq}}^2} \right), \tag{9} \]

where the power-law index is \( q = 3\sigma/(\sigma - 1) \) and \( f_{\text{inj}} \) is the amplitude at \( p = p_{\text{inj}} \) (Kang 2011). The cutoff momentum can be derived from the equilibrium condition that the DSA momentum gains per cycle are equal to the synchrotron/iC losses per cycle (Kang 2011):

\[ p_{\text{eq}} = \frac{m_e^2 c^3 u_e}{\sqrt{4\pi e^4 q/27}} \left( \frac{B_1}{B_{e1}^2 + B_{e2}^2} \right)^{1/2}. \tag{10} \]

The corresponding Lorentz factor for typical clusters shock parameters is then

\[ \gamma_{e,\text{eq}} \approx \frac{2 \times 10^9}{q^{1/2} \left( \frac{3000 \text{ km s}^{-1}}{u_e} \right) \left( \frac{B_1}{B_{e1}^2 + B_{e2}^2} \right)^{1/2}}. \tag{11} \]

Postshock electrons cool radiatively while adverting downstream, so the electron spectrum cuts off at a progressively lower momentum away from the shock. As a result, the volume integrated electron energy spectrum, \( F_e(p) \), becomes steeper than the power-law in Eq. (9) by one power of the momentum above the ‘break momentum’ \((p > p_{e,\text{br}})\). At the shock age \( t \), the ‘break Lorentz factor’ can be estimated from the condition \( t_{\text{age}} = t_{\text{rad}} = p/b(p)\):

\[ \gamma_{e,\text{br}}(t) \approx 10^4 \left( \frac{t_{\text{age}}}{10^{10} \text{ yr}} \right)^{-1} \left( \frac{B_{e,2}}{5 \text{ uG}} \right)^{-2}. \tag{12} \]

The synchrotron emission from mono-energetic electrons with \( \gamma_e \) peaks around the frequency \( \nu_{\text{peak}} \approx 0.3(3eB/4\pi m_e c)^{1/2} \), so it will be useful to have the following relation:

\[ \nu_{\text{peak}} \approx 0.63 \text{GHz} \left( \frac{\gamma_e}{10^4} \right)^2 \left( \frac{B}{5 \text{ uG}} \right). \tag{13} \]

Then the synchrotron radiation spectrum emitted by the electron population of the power-law given in Eq. (9) also has a power-law form of \( j_\nu \propto \nu^{-\alpha_\nu} \) with \( \alpha_\nu = (q - 3)/2 \).

For diffuse radio structures such as radio halos and radio relics with \( B \sim 5 \text{ uG} \) and the radio flux density, \( S_\nu \sim 5 \text{ mJy} \), the optical depth for synchrotron emission is small for the frequencies considered here \((\nu > 10 \text{ MHz})\) (Jones et al. 1974; Lang 1999). So the synchrotron self-absorption can be ignored in the calculation of synchrotron radiation spectrum of the model shocks.

3. DSA SIMULATION RESULTS

3.1 Planar versus Spherical Shocks

In this section we compare the the electron acceleration at a spherical shock with that at a planar shock with similar properties. First, the planar shock is characterized by the following parameters: the shock speed, \( u_s = 3.5 \times 10^4 \text{ km s}^{-1} \), the sonic Mach number, \( M_s = 4.5 \), the preshock density, \( n_H = 10^{-3} \text{ cm}^{-3} \), and the preshock and postshock magnetic field strength, \( B_1 = 2 \mu \text{G} \) (for \( x > x_s \)) and \( B_2 = 7 \mu \text{G} \) (for \( x < x_s \)).

In the upper panel of Fig. 2, we show the spatial profiles of the electron distribution function, \( g_e(\gamma_e) \) for different energies, \( \log \gamma_e = 3.3, 3.7, 4.0, 4.3, 4.5, \) and 4.8. Note that the shock location is shifted slightly from left to right at later time epochs, \( t_{\text{age}} = (1.8, 4.4, 8.0) \times 10^7 \text{ yr} \). The downstream width of \( g_e, L(\gamma_e) \), for low energy electrons with \( \log \gamma_e \lesssim 3.3 \) increases simply as \( t_{\text{d}2}/(u_e/\sigma) t_{\text{age}} \approx 100kpc(t_{\text{age}}/10^8 \text{ yr}) \). For high energy electrons, on the other hand, \( L(\gamma_e) \) decreases with \( \gamma_e \), since the radiative cooling time scales inversely with energy as in Eq. (4). As can be seen in the figure, for \( t_{\text{age}} > 4.4 \times 10^7 \text{ yr} \), for instance, the width \( L(\gamma_e) \) for \( \gamma_e \gtrsim 10^4 \) becomes constant in time \( (t_{\text{age}} > t_{\text{rad}}) \) as \( L(\gamma_e) \approx (u_e/\sigma) t_{\text{rad}}(\gamma_e) \) (see blue dashed, green dot-dashed, magenta dot-long dashed, and cyan dash-long dashed lines).

From Eq. (13), the electrons with \( \gamma_e \) are expected to have the peak of synchrotron emission at \( \nu_{\text{peak}} \approx 1 \text{GHz}(\gamma_e/10^4)^2 \). The middle panel of Fig. 2 shows the synchrotron emissivity, \( j_\nu \), for the peak frequency that corresponds to the Lorentz factor chosen for the upper panel (i.e. \( \log \gamma_e = 7.6, 8.5, 9.0, 9.6, 10.0, \) and 10.7), at the same epochs as in the upper panel. Note that the spatial distribution of synchrotron emission at \( \nu_{\text{peak}} \) is much broader than that of electrons with the corresponding \( \gamma_e \). This is because more abundant lower energy electrons also contribute significantly to the synchrotron emissivity at \( \nu_{\text{peak}} \). For example, the spatial profile of \( j_\nu(1\text{GHz}) \) (blue dashed lines) is much broader and decreases much gradually, compared to that of \( g_e \) of the corresponding \( \gamma_e = 10^4 \) (also blue dashed lines) with \( L(\gamma_e = 10^4) \approx 40kpc \). So the downstream width of synchrotron emitting volume would be greater than that of the spatial distribution of \( g_e(\gamma_e) \) for the value of \( \gamma_e \) related by Eq. (13), that is, \( L(\nu_{\text{peak}}) > L(\gamma_e) \), if the width is constrained by the cooling time \( t_{\text{rad}} \). Note that \( g_e \) and \( j_\nu \) are plotted in arbitrary units in Fig. 2.

The bottom panel of Fig. 2 shows the spectral slopes which are defined as

\[ \alpha = \frac{\log \nu_1 - \log \nu_2}{\log \nu_2 - \log \nu_1} = -\frac{d \ln j_\nu}{d \ln \nu} \tag{14} \]

estimated between \( \nu_1 \) and \( \nu_2 \). The peak frequencies chosen in the middle panel are adopted for \( \nu_1 \) and \( \nu_2 \), so \( \alpha_{7.6-8.5} \) (black solid line), \( \alpha_{8.5-9.0} \) (red dotted), \( \alpha_{9.0-9.6} \) (blue dashed), \( \alpha_{9.6-10} \) (green dot-dashed), and \( \alpha_{10-10.7} \) (magenta dot-long dashed) are plotted. The
characteristic scale over which $\alpha_{\log \nu_1 - \log \nu_2}$ increases is governed mainly by the length scale of $j_{\nu}$ at the higher frequency $\nu_2$. For example, the slope $\alpha_{9.0-9.6}$ (blue dashed line in the bottom panel) behaves similarly to the emission $j_{\nu}$ at $\log \nu = 9.6$ (green long dashed line in the middle panel).

For the spherically expanding shock, we adopt a Sedov-Taylor similarity solution with the shock speed, $u_s = u_o(t/t_o)^{-3/5}$, as the initial set up. Here $t_i$ is the initial time from which electrons are injected at the shock and $u_o = 2.3 \times 10^3 \text{ km s}^{-1}$ and $t_o = 1.73 \times 10^9 \text{ yr}$. For $t_i = 0.5 t_o$, the initial shock speed, $u_{s,i} \approx 3.5 \times 10^3 \text{ km s}^{-1}$ and $M_s = 4.5$, which are similar to the parameters for the planar shock shown in Fig. 2. Since the sonic Mach number is not large and the shock compression ratio is $\sigma = \rho_2/\rho_1 = 3.5$, the shock evolution behaves slightly differently from the true Sedov-Taylor solution. So at later time the shock speed evolves only approximately as $u_s(t) \approx u_o(t/t_o)^{-3/5}$.

Again note that only the structure and evolution of the flow velocity $u(r, t)$, is fed into the diffusion convection Eq. (1) and the other gasdynamical variables do not influence the DSA process. For the comparison with the planar shock, the magnetic field strengths are assumed to be constant in both space and time with $B_1 = 2 \mu \text{G}$ and $B_2 = 7 \mu \text{G}$. In the next section, we will consider several models with variable magnetic field strength, $B(r, t)$ behind the shock.

The characteristics of the spherical shock model shown in Fig. 3 can be compared directly with those of the planar shock shown in Fig. 2. Here the results are shown at the time elapsed from the initial injection,
DECELERATING SPHERICAL CLUSTER SHOCK

Fig. 3.— Time evolution of the spherical shock of $u_s = 2.3 \times 10^3$ km s$^{-1}(t/t_o)^{-3/5}$, $M_s = 3.0(t/t_o)^{-3/5}$, and $B_2 = 7 \mu$G (where $t_o = 1.73 \times 10^8$ yr) are shown for $t_{age} = (1.7, 4.3, 8.7) \times 10^7$ yr (from left to right). Electrons are injected at the shock from $t_i = 0.5t_o$ when $u_{s,i} = 3.5 \times 10^3$ km s$^{-1}$. Top: Spatial distributions of $g_e(\gamma_e)$. Middle: Spatial distributions of $j_\nu(\nu)$. Bottom: Spectral slopes of $\alpha_{\log \nu_1 - \log \nu_2}$. The line types are the same as in Fig. 2.

$\log \gamma_e$ = 3.3, 3.7, 4.0, 4.3, 4.5, 4.8

$\log \nu$ = 7.6, 8.5, 9.0, 9.6, 10., 10.7

$\alpha_{\log \nu_1 - \log \nu_2}$

$t_{age} \equiv (t - t_i) = (1.7, 4.3, 8.7) \times 10^7$ yr, during which the shock speed decreases from $3.5 \times 10^3$ km s$^{-1}$ ($M_s = 4.5$) to $1.5 \times 10^3$ km s$^{-1}$ ($M_s = 3.1$). The obvious feature, which is different from the planar shock case, is that the injected particle flux decreases as the spherical shock slows down in time. As a result, the amplitude of $g_e(\gamma_e)$ increases downstream away from the shock at a given time, especially in the case of low energy electrons, which simply advect downstream without much cooling. So low frequency ($\nu \leq 360$MHz) radio emission may increase towards downstream as well. For high energy electrons, on the other hand, the decline of $g_e(\gamma_e)$ due to cooling dominates over the effect of decreasing injection flux. Thus radio emission at higher frequencies ($\nu \geq 1$GHz) should decrease downstream behind the shock. Again note that $g_e$ and $j_\nu$ are plotted in arbitrary units in Fig. 3.

Similarly to the planar shock model, the spatial distribution of synchrotron emission at $\nu_{peak}$ is much broader than that of $g_e(\gamma_e)$ for the corresponding $\gamma_e$. For example, again the width of $g_e$, $L(\gamma_e = 10^4) \approx 40$kpc (blue dashed line in the top panel), while the width of $j_\nu$, $L(\nu \approx 1$GHz) $\approx 100$kpc (blue dashed line in the middle panel). But the slope $\alpha_{9.0-9.6}$ between 1GHz and 4GHz (blue dashed line in the bottom panel) follows the spatial profile of the emission $j_\nu$ at 4GHz (green dot-dashed line in the middle panel). Thus the main difference between a planar shock and a decelerating spherical shock is the decline of the injected particle flux in time, leading to possible increase of low frequency radio emission toward the downstream away from the shock.

Next we attempt to find any spectral signatures imprinted in the synchrotron emission spectrum in the case of the spherical shock case. In the left panels of Fig. 4, we show at the three epochs the electron spectrum at the shock, $g_e(x_s, p)$, and the volume integrated electron spectrum $G_e(p) = \int p^2 F_e(p)$, where $F_e(p) = \int j_\nu(p) d\nu$. The line types are the same as in Fig. 2.
Fig. 4.— Electron (left) and synchrotron (right) spectral properties for the planar shock shown in Fig. 2 are shown for \( t = (1.8, 4.4, 8.0) \times 10^7 \) yr (solid, dotted, and dashed lines). Upper left: electron distribution function at the shock position, \( g_e(x_s, p) = p^4 f_e(x_s, p) \), and integrated over the simulation volume, \( G_e(p) = p^4 F_e \). Lower left: electron distribution slopes, \( q = - \partial \ln f_e(x_s) / \partial \ln p \), and \( Q = - \partial \ln F_e / \partial \ln p \). Upper right: synchrotron radiation spectrum at the shock position, \( \nu J_\nu(x_s) \), and integrated over the simulation volume, \( \nu J_\nu \). Lower right: synchrotron spectral slope, \( \alpha_\nu \), for \( j_\nu(x_s) \) and \( A_\nu \) for \( J_\nu \).

\[ \int f_e(p, x) dx \text{, and their slopes, } q = - \partial \ln f_e(x_s) / \partial \ln p, \text{ and } Q = - \partial \ln F_e / \partial \ln p. \] The slope from the simulation results is consistent with the test-particle slope \( q = 4.2 \) for \( \sigma = 3.5 \), and the slope for the volume integrated spectrum, \( Q = q + 1 \), above the break momentum \( p_{e,br} \). Note that \( \gamma_e = p/m_e c \) for relativistic energies. As can be seen in Fig. 4, the electron energy spectrum at the shock has reached the steady state at these ages. The volume integrated spectrum shows the gradual decline of the break Lorentz factor, \( \gamma_{e,br} \) with the shock age.

The same kinds of quantities for the spherical shock are shown in the left panels of Fig. 5. We can see the time evolutions of the electron spectrum as the shock slows down in time. Since the shock Mach number decreases, the slope \( q \) for \( g_e(r_s, p) \) increases in time, leading to a nonlinear change of the volume integrated spectrum, \( G_e(p) \). So the slope \( Q \) no longer follows the simple \( q + 1 \) steepening above \( p_{e,br} \). In addition to usual radiative cooling, both reduced injected particle flux and steepening of \( g_e(r_s, p) \) due to slowing-down weakening shock affect the spectral shape of \( G_e(p) \).

In addition, we show the synchrotron emission spectrum at the shock, \( j_\nu(x_s) \) in Fig. 4 and \( j_\nu(r_s) \) in Fig. 5, and the volume integrated emission spectrum, \( J_\nu = \int j_\nu(x) dx \) in Fig. 4 and \( J_\nu = \int j_\nu(r) 4\pi r^2 dr \) in Fig. 5. Their respective slopes, \( \alpha_\nu = - d \ln j_\nu / d \ln \nu \) and \( A_\nu = - d \ln J_\nu / d \ln \nu \) are shown in the lower right panels of Figs. 4 and 5. For the planar shock with \( \sigma = 3.5 \), the test-particle slope is \( \alpha_\nu = 0.6 \) and \( A_\nu = \alpha_\nu + 0.5 = 1.1 \), as can be seen in Fig. 4. We note that the transition of the radiation slope from \( A_\nu = \alpha_\nu \) to \( A_\nu = \alpha_\nu + 0.5 \) is more gradual, compared to the transition of the particle slope from \( Q = q \) to \( Q = q + 1 \). For the shock parameters chosen here, at the shock age of \( \sim 10^8 \) yr this transition occurs over the broad frequency range, \( 0.01 \text{GHz} \leq \nu \leq 1 \text{GHz} \).

For the spherical shock shown in Fig. 5, on the other
DECELERATING SPHERICAL CLUSTER SHOCK

Fig. 5.— Same as Fig. 4 except that the results for the spherical shock shown in Fig. 3 are plotted at $t_{\text{age}} = (1.7, 4.3, 8.7) \times 10^7 \, \text{yr}$ (solid, dotted, and dashed lines).

3.2 Spherical Shocks with Different Magnetic Field Models

Self-excitation of MHD waves and amplification of magnetic fields via plasma instabilities are the integral parts of DSA at strong collisionless shocks. CRs streaming upstream in the shock precursor excite resonant Alfvén waves with wavelengths comparable with the CR proton gyroradii, and turbulent magnetic fields can be amplified into the nonlinear regime (Bell 1978; Lucek & Bell 2000). In addition, the nonresonant fast-growing instability driven by the CR current can amplify the magnetic field by orders of magnitude (Bell 2004; Riquelme & Spitkovsky 2009). It was shown that, in the case of strong shocks ($M_s > 10$), magnetic amplification (MFA) via streaming instabilities and Alfvénic drift can lead to significant nonlinear feedback to the shock structure and the predicted CR spectrum (e.g. Caprioli 2012; Kang 2012).

In a recent study of hybrid plasma simulations, Caprioli & Spitkovsky (2014b) has shown that the MFA factor increases with the Alfvénic Mach number as $\langle \delta B/B \rangle^2 \sim 3M_A(F_{cr,2}/\rho_1 u_s^2)$, where $\delta B$ is the turbulent magnetic fields perpendicular to the mean background magnetic fields. For the sonic Mach number in the range of $3 \leq M_s \leq 5$, the CR proton acceleration efficiency varies as $F_{cr,2}/\rho_1 u_s^2 \sim 0.01 - 0.05$ (Kang & Ryu 2013; Caprioli & Spitkovsky 2014a). For the typical cluster shocks with $M_A \sim 10$, the MFA factor due to the streaming instabilities is expected to be rather small, $(\delta B/B)^2 \sim 0.3 - 1.5$. But it has not been studied fully yet how magnetic fields can be amplified at weak shocks in high beta ICM plasmas. As in the previous study of Kang et al. (2012), we adopt the postshock...
Fig. 6. — Spherical shock models with three different magnetic field profiles: MF1, MF2, and MF3. The results are shown at \( t_{\text{age}} = 1.3 \times 10^8 \) yr, when \( u_s = 2.5 \times 10^3 \) km s\(^{-1}\) and \( M_s = 2.4 \). Spatial distributions of the electron distribution function, \( g_e(\gamma_e) \), the synchrotron emissivity, \( j_\nu(\nu) \), the spectral slope, \( \alpha = \log \nu_1 - \log \nu_2 \), and magnetic field strength, \( B(r) \) (from top to bottom panels). The line types for \( g_e(\gamma_e), j_\nu(\nu), \) and \( \alpha = \log \nu_1 - \log \nu_2 \) are the same as in Figs. 2 and 3. Note that \( g_e \) and \( j_\nu \) are plotted in arbitrary units.

In MF2 and MF3 models, the postshock magnetic field energy is assumed to be dissipated, and so \( B(r) \) decreases with the gas pressure or density behind the shock. As shown in the bottom panels of Fig. 6, the decay length scale is about 100-150 kpc in MF2 and MF3 models.

As in the previous section, we consider a blast-wave, \( u_s \approx u_o(t/t_o)^{-3/5} \), where \( u_o = 3.0 \times 10^3 \) km s\(^{-1}\) and \( t_o = 1.3 \times 10^8 \) yr (slightly faster than the shock adopted in Fig. 3). The calculations started at \( t_i = 0.5t_o \) with \( u_{s,i} \approx 4.5 \times 10^3 \) km s\(^{-1}\) and \( M_i \approx 4.3 \) and ended at \( t_f = 1.5t_o \) with \( u_{s,f} \approx 2.5 \times 10^3 \) km s\(^{-1}\) and \( M_f \approx 2.4 \). The results of these three models at the final time \( (t_{\text{age}} = t - t_i \approx 1.3 \times 10^8 \) yr) are compared in Fig. 6.
As in the spherical shock model shown in Fig. 3, the spatial profile of \( g_e \) for low energy electrons increases downstream away from the shock. The distributions of \( g_e(\gamma_e \approx 5 \times 10^3) \) (red dotted lines) show some differences among the three models due to different synchrotron cooling rates. The spatial profiles of \( j_\nu \) at low frequencies (e.g. 360MHz in red dotted lines) show rather weak dependences on the \( B(r) \) model, while those at higher frequencies (e.g. 1GHz in blue dashed lines) behave similarly in all three models. Moreover, the steepening patterns of \( \alpha_\nu \) behind the shock show no significant differences among the three models.

Thus it may be difficult to differentiate the post-shock magnetic field profile from the spatial variation of spatially resolved radio flux, \( S_\nu \), or spectral slope, \( \alpha_\nu \). In other words, signatures imprinted on synchrotron emission due to different \( B(r) \) behind the shock would be too subtle to detect. There are two reasons that may explain this prediction. Because the IC cooling with \( B_{\text{rad}} = 4.7 \mu G \) provides the baseline for the cooling rate, \( b(p) \), the difference in the synchrotron cooling due to different \( B(r) \) has relatively minor effects. Also any sharp features in the distribution of \( f_e(r,p) \) would be smeared out in the distribution \( j_\nu(r) \), since the synchrotron emission at a given frequency comes from electrons with a somewhat broad range of \( \gamma_e \).

Finally, in Fig. 7 we compare the synchrotron radiation spectrum at the shock, \( j_\nu(r_s) \), and the volume integrated radiation spectrum, \( J_\nu \), for the three magnetic field models at \( t_{\text{age}} = 0.33, 0.67, 1.3 \times 10^8 \) yr. Departures from the predictions for the test-particle planar shock are most severe in MF1 model, while it becomes relatively milder in the two models with decaying \( B(r) \) behind the shock. As expected, any variations in the spatial profiles of \( f_e(r,p) \) and \( B(r) \) should be averaged out in the volume integrated quantities such as \( F_e(p) \) and \( J_\nu \).

In conclusion, any features in the spectral curvature, \( dA_\nu/d\nu \), or the steepening of spectral slope, \( d\alpha_\nu/dr \), in the postshock region, should be affected in principle by both the time-dependent evolution of the shock and the spatial variation of postshock magnetic fields. But the effect of decaying magnetic fields may be too subtle to detect due to dominance of IC scattering on CBR.
4. SUMMARY

We have performed time-dependent DSA simulations for cosmic-ray (CR) electrons at a planar shock with a constant speed and decelerating spherical shocks similar to Sedov-Taylor blast waves. These shocks have the parameters relevant for weak cluster shocks typically found in the outskirts of galaxy clusters: $u_s \approx (1.5-4.5) \times 10^3 \text{ km s}^{-1}$, $M_s \approx 2.5-4.5$, $B_1 \approx 2-3 \mu \text{G}$, and $B_2 \approx 7 \mu \text{G}$. For spherical shocks, we used one dimensional spherical version of CRASH code, in which a co-expanding spherical grid was adopted in order to optimize the shock tracking and adaptive mesh refinement features (Kang & Jones 2006). The diffusion convection equation for the pitch-angle-averaged phase space distribution function for CR electrons in the test-particle regime was solved along with the usual gasdynamic conservation equations without including the dynamical feedback of the CR proton pressure. Then the synchrotron emission from CR electrons accelerated at these model shocks were estimated by adopting several models for magnetic field profile, $B(r)$, and the electron energy spectrum, $N_e(r, \gamma_e)$ from the DSA simulations.

Since the time scales for electron acceleration and cooling are much shorter than the dynamical time scale, the electron energy spectrum at the shock, $f_e(r, p, t)$, has reached the steady state in the planar shock model, as can be seen in Fig. 4. The slope of the volume-integrated momentum distribution, $F_e(p)$, is simply $Q = q + 1$ above the break momentum ($p > p_{\text{br}}$), while the slope of the volume-integrated synchrotron emission spectrum, $J_\nu$, is $A_\nu = \alpha_\nu + 0.5$ above the break frequency ($\nu > \nu_{\text{br}}$). They are consistent with the predictions of the DSA theory in the test-particle limit.

In the spherical shock cases, the electron energy spectrum at the shock has reached the steady state defined by the instantaneous shock parameters (i.e. $u_s(t)$, $r_s(t)$ and $M_s(t)$), as shown in Fig. 5. So the synchrotron radiation spectra at the shock location could be described properly by the test-particle DSA predictions. However, the volume integrated spectra of $F_e(p, t)$ and $J_\nu(\nu, t)$ both evolve differently from those of the planar shock, depending on the time-dependent evolution of the shock parameters. As a result, the slopes, $Q$ and $A_\nu$, exhibit some nonlinear signatures that come from decreasing particle flux and declining shock Mach number (see Fig. 5). This suggests that, in the case of evolving shocks, one needs to be cautious about interpreting observed radio spectra by adopting simple DSA models in the test-particle regime.

In addition, we have considered spherical shock models with decaying postshock magnetic fields, in which $B(r)$ decreases behind the shock with a scale height of 100-150 kpc, as shown in Fig. 6. Because inverse-Compton scattering of cosmic background radiation with $B_{\text{rad}} \approx 4.7 \mu \text{G}$ (for $z = 0.2$ adopted here as a reference epoch) provides the base-line cooling, the electron energy spectrum do not depend sensitively on the $B(r)$ profile. We also find that the impacts of the different $B(r)$ profile on the spatial profile of synchrotron emission, $J_\nu(r)$ and its slope, $\alpha_\nu(r)$ is rather minimal, since electrons in a somewhat broad range of $\gamma_e$ contribute emission to $J_\nu$ at a given frequency. Of course, any nonlinear features due to the spatial variations in $f_e(r, p)$ and $B(r)$ will be mostly averaged out and may leave only subtle signatures in the volume integrated spectrum, $J_\nu$, and it slope, $A_\nu$.
