Abstract. Graves’ ophthalmopathy (GO) is characterized by an autoimmune reaction against thyrotropin (TSH) receptors and is diagnosed by TSH receptor antibody (TRAb). A novel assay for thyroid-stimulating antibody (TSAb) was recently introduced using a frozen Chinese hamster ovary cell line expressing TSH receptors, cyclic adenosine monophosphate (cAMP)-gated calcium channel, and aequorin (aequorin TSAb). The aim of this study was to evaluate the role of aequorin TSAb in GO. We studied 136 Japanese patients with GO (22 euthyroid and 8 hypothyroid GO patients) at our hospital. TRAbs were estimated by first generation TRAb (TRAb 1st), second generation TRAb (hTRAb 2nd), conventional porcine TSAb, and the new aequorin TSAb assays. Aequorin TSAb, porcine TSAb, TRAb 1st, and hTRAb 2nd were positive in 125/136 (92%), 110/136 (81%), 81/130 (62%), and 93/114 (82%) patients, respectively. In patients with hyperthyroid GO, they were positive in 98/106 (98%), 96/106 (91%), 78/101 (77%), and 84/93 (90%) patients, respectively. In patients with euthyroid GO, they were positive in 19/22 (86%), 9/22 (41%), 1/21 (5%), and 6/17 (35%) patients, respectively. Aequorin TSAb levels were significantly related to TRAb 1st (r = 0.4172, p < 0.0001), hTRAb 2nd (r = 0.2592, p < 0.0001), and porcine TSAb (r = 0.4665, p < 0.0001). Clinical activity score (CAS) was significantly greater in patients with high titers of aequorin TSAb than in those with low titers. Aequorin TSAb levels were significantly related to the signal intensity ratio of the enlarged eye muscle and proptosis evaluated by MRI before steroid pulse therapy. Aequorin TSAb assay was more sensitive than the conventional assays, especially in euthyroid GO.

Key words: Graves’ ophthalmopathy, Thyrotropin receptor antibody, Thyroid-stimulating antibody, Aequorin
sitive than the conventional assays for Graves’ disease [12]. The aim of this study was to evaluate the role of aequorin TSAb in GO.

Materials and Methods

We studied 136 Japanese patients with GO (mean age 53 yr, range 27–81 yr, 86 females) who visited the Kurume University Hospital and Kurume University Medical Center between 2011 and 2015. At the time of diagnosis of ophthalmopathy, 106 patients had hyperthyroidism, 22 were euthyroid (euthyroid GO), and 8 had hypothyroidism without any history of hyperthyroidism (hypothyroid GO). Among them, fifty patients received methylprednisolone pulse therapy for moderate to severe, or sight-threatening and active GO and were followed for >1 year in our hospital. Ophthalmological examinations and magnetic resonance imaging (MRI) were performed at baseline, and at 53 yr, range 27–81 yr, 86 females) who visited the Kurume University Hospital and Kurume University Medical Center between 2011 and 2015. At the time of diagnosis of ophthalmopathy, 106 patients had hyperthyroidism, 22 were euthyroid (euthyroid GO), and 8 had hypothyroidism without any history of hyperthyroidism (hypothyroid GO). Among them, fifty patients received methylprednisolone pulse therapy for moderate to severe, or sight-threatening and active GO and were followed for >1 year in our hospital. Ophthalmological examinations and magnetic resonance imaging (MRI) were performed at baseline, and at 1, 6, and 12 months after pulse therapy, as previously described [13, 14].

Informed consent was obtained from the patients and the ethical approval was obtained from the Ethical Committee of Kurume University.

Laboratory assays

TRAb estimation was performed by the first generation TRAb (TRAb 1st, TRAb Cosmic III kit, Cosmic Co., Japan) with a cutoff value of 10%, the second generation assay (TRAb 2nd, DYNO test TRAb Human kit ‘Yamasa’; Yamasa Co., Choshi, Chiba, Japan) with a cutoff value of 1.0 IU/L, the conventional TSAb kit ‘Yamasa’ (Yamasa) with a cutoff value of 180%, and the new aequorin TSAb assay (Otsuka Pharmaceutical Co., Ltd. Minato-ku, Tokyo, Japan) with a cutoff value of 35 mIU/L, as previously reported [12].

Ophthalmological examinations

Ophthalmological examinations were performed by two expert ophthalmologists for GO using the modified NOSPECS classification [15] and CAS [16]. Proptosis was assessed with a Hertel exophthalmometer. The ocular movements were evaluated with a Hess chart. The alterations of eye symptoms were recorded based on an ophthalmopathy index according to the American Thyroid Association classification for eye sign changes in GO. The ophthalmopathy index was calculated as the sum of the scores (0–3) for each class ranging from 0 to 15 [17]. The CAS was graded according to the modified CAS system developed by the European Group on Graves’ orbitopathy (EUGOGO) [16].

Magnetic resonance imaging

MRI of the orbits was performed in the parasagittal, horizontal, and coronal planes with a 3.0-T superconducting MR unit (MAGNETOM Skyra, Siemens) having a surface coil (eye coil). The thickness of the superior, medial, and inferior rectus muscle was estimated at the site of their enlargement in the coronal section of the T1-weighted image. The thickness of the lateral rectus muscle was estimated at the site of its enlargement in a horizontal section of the T1-weighted image. The enlargement of the eye muscle was also expressed as a ratio of the thickness of the eye muscle to the diameter of the optic nerve to avoid individual variation. The signal intensity of the enlarged ocular muscle was also measured at the site of enlargement in the Short T1 Inversion Recovery (STIR) image and was compared to that of the cerebral substantia alba, expressing as the signal intensity ratio [14]. Proptosis was also determined as the distance between the corneal eminence and the line connecting the two zygomatic bones in a horizontal section of the T1-weighted image. Muscle measurement was performed on the same muscle and the same section.

Protocol of the steroid pulse therapy

Methylprednisolone was administered for 3 days at a daily dosage of 0.5 or 1 g diluted in 500 mL isotonic saline infused intravenously over 2 h [18]. The patients were treated thrice repeatedly. Ophthalmological examination was performed within one week after the last cycle of pulse therapy. Ophthalmological examinations and MRI were also performed at 6 and 12 months after the pulse therapy, as previously described.

Statistical analysis

The continuous variables were compared between the two groups using the t-test or Wilcoxon rank-sum test, while the categorical variables were analyzed using the chi-square test or Fisher’s exact probability test. The relationship between aequorin TSAb and porcine TSAb or TRAbs was examined by linear correlation analysis. A p-value <0.05 was considered statistically significant. All statistical analyses were performed using JMP software (JMP® pro12.2.0, SAS Institute Inc., SAS Campus Drive, Cary, NC, USA).

Results

Prevalence of anti-TSH receptor antibody in Graves’ ophthalmopathy

The aequorin TSAb, conventional porcine TSAb, TRAb 1st, and hTRAb 2nd were positive in 125/136 (92%), 110/136 (81%), 81/130 (62%), and 93/114 (82%) patients with ophthalmopathy, respectively (Table 1).
The positive ratio in aequorin TSAb assay was significantly greater than that in conventional porcine TSAb, TRAb 1st, or TRAb 2nd generation assay. In patients with euthyroid GO, aequorin TSAb, conventional porcine TSAb, TRAb 1st, and hTRAb 2nd were positive in 19/22 (86%), 9/22 (41%)*, 1/21 (5%)*, and 6/17 (35%)* patients, respectively. The positive ratio in aequorin TSAb assay was significantly greater than that in conventional porcine TSAb, TRAb 1st, or TRAb 2nd generation assay.

Correlation between aequorin TSAb and TRAb 1st, human TRAb 2nd and porcine TSAb

The aequorin TSAb levels were significantly related to the signal intensity ratio of the enlarged extraocular muscles and proptosis evaluated by MRI before steroid pulse therapy (Fig. 2).

Table 1

| Prevalence of anti-TSH receptor antibodies in patients with Graves' ophthalmopathy (N = 136). |
|---------------------------------|---------------------------------|---------------------------------|---------------------------------|---------------------------------|
| **Normal range**                | Aequorin TSAb | 35 mIU/L | Porcine TSAb | 180% | TRAb 1st | <15% | hTRAb 2nd | <1.0 IU/L |

*p < 0.05, **p < 0.01, ***p < 0.005, ****p < 0.001.

The positive ratio in aequorin TSAb assay was significantly greater than that in conventional porcine TSAb, TRAb 1st, or TRAb 2nd generation assay. In patients with euthyroid GO, aequorin TSAb, conventional porcine TSAb, TRAb 1st, and hTRAb 2nd were positive in 19/22 (86%), 9/22 (41%), 1/21 (5%), and 6/17 (35%) patients, respectively. The positive ratio in aequorin TSAb assay was significantly greater than that in conventional porcine TSAb, TRAb 1st, or TRAb 2nd generation assay.

Correlation between aequorin TSAb and TRAb 1st, human TRAb 2nd and porcine TSAb

The aequorin TSAb levels were significantly related to the signal intensity ratio of the enlarged extraocular muscles and proptosis evaluated by MRI before steroid pulse therapy (Fig. 2).

Relationship between aequorin TSAb and orbital findings before pulse therapy for GO

The aequorin TSAb levels were significantly related to the signal intensity ratio of the enlarged eye muscle and proptosis evaluated by MRI before steroid pulse therapy (Fig. 2).

Relationship between aequorin TSAb and changes in orbital findings assessed by MRI after pulse therapy (N = 50)

Significant improvements in the size and signal intensity ratio of the enlarged extraocular muscles were observed in GO patients with an either high or low titer of aequorin TSAb (Table 3). The improvement persisted up to 1 year. In contrast, proptosis and retro-orbital vol-
ume were improved in GO patients with high titers of aequorin TSAb at 1 month after the pulse therapy, but the values exacerbated at 6 months after the pulse therapy.

**Discussion**

In the present study, the highest sensitivity of aequorin TSAb was obtained in GO, especially in euthyroid GO (86%), whereas that of porcine TSAb, TRAb 1st, and hTRAb 2nd were 41%, 5%, and 35%, respectively. These results suggest the usefulness of aequorin TSAb for early diagnosis, making the decision for treatment, and monitoring treatment in GO, especially in euthyroid GO. A previous study showed that aequorin TSAb assay has wider ranges in the measurement and have a shorter assay time [13]. Aequorin TSAb assay directly detects intra-cellular cAMP increase via cyclic nucleotide-gated ion channels on the cell membrane without homogenization, which may increase its sensitivity. The intra-assay and interassay variation in aequorin TSAb assay was low enough to be acceptable for the routine use [13]. Furthermore, it does not require a sterilized culture system. This assay, therefore, may be beneficial for use in the general clinical laboratories.

There are several reports demonstrating the association of TRAbs with ophthalmopathy. Noh et al. reported that the severity of ophthalmopathy was associated with TSAb but not thyrotropin-binding inhibitor immunoglobulin (TBII) [8]. Eckstein et al. showed a positive association of the second-generation TBII assay based on the human recombinant TSH receptor (hTRAb 2nd) with the severity of ophthalmopathy [9]. Lytton et al. reported thyroid stimulating immunoglobulin (TSI) bioassay in a cross-sectional study using CHO cell expressing the chimeric human TSH receptor, which had amino acids 262 to 335 substituted with 73 amino acids from the rat LH receptor (Mc4/CHO) [10]. They found that TSI was positive in 97% of GO, and the TSI level correlated with the CAS. They suggested that TSI is a clinically useful tool for the management of patients with GO [11]. Furthermore, the present study showed the positive association between the aequorin TSAb levels and orbital findings quantitatively assessed by MRI. The proptosis and enlargement of eye muscles assessed by MRI were greater in patients having a high titer of aequorin TSAb. These results suggest the aequorin TSAb level may be a promising biomarker for GO.

This study has some limitations. First, it was a cross-sectional study and retrospective in design. There was not adequate data related to the outcome of ophthalmopathy post therapy. Second, the number of included patients was small, which also prevented us from arriv-
ing at definite conclusions. Third, there were no functional studies on the pathological mechanisms of GO. However, our studies showed some positive association of aequorin TSAb and the effect of pulse therapy on different orbital findings. We, therefore, emphasized the clinical usefulness of this new assay and the importance of prospective monitoring during conventional treatment or new pharmacological treatments for GO [19, 20]. Further prospective studies are indicated to clarify the usefulness of this assay to assess the occurrence or progression of ophthalmopathy. Studies are also required to aid in the decision making for the treatment of GO, in the prediction of response to therapy, and in assessing recurrence of ophthalmopathy after therapy. A study on the role of aequorin TSAb on the occurrence or exacerbation of ophthalmopathy after 131I therapy for Graves’ disease is being presently undertaken by our study group.

In conclusion, the aequorin TSAb assay was more sen-

Table 3 Relationship between aequorin TSAb and changes in the orbital findings assessed by MRI after pulse therapy.
