Abstract

Invasive cancer causes a change in density in the affected tissue, which can be visualized by x-ray phase-contrast tomography. However, the diagnostic value of this method has so far not been investigated in detail. Therefore, the purpose of this study was, in a blinded manner, to investigate whether malignancy could be revealed by non-invasive x-ray phase-contrast tomography in lymph nodes from breast cancer patients. Seventeen formalin-fixed paraffin-embedded lymph nodes from 10 female patients (age range 37–83 years) diagnosed with invasive ductal carcinomas were analyzed by X-ray phase-contrast tomography. Ten lymph nodes had metastatic deposits and 7 were benign. The phase-contrast images were analyzed according to standards for conventional CT images looking for characteristics usually only visible by pathological examinations. Histopathology was used as reference. The result of this study was that the diagnostic sensitivity of the image analysis for detecting malignancy was 100% and the specificity was 87%. The positive predictive value was 91% for detecting malignancy and the negative predictive value was 100%. We conclude that x-ray phase-contrast imaging can accurately detect density variations to obtain information regarding lymph node involvement previously inaccessible with standard absorption x-ray imaging.

Introduction

Breast cancer is the leading cause of death in cancer among women [1]. Early diagnosis and accurate staging of the disease are crucial for proper treatment and improved prognosis. It is of major importance whether the cancer is confined to the breast or has spread to the adjacent lymph nodes. The current state-of-the-art method to investigate the regional axillary lymph nodes is the sentinel node (SNL) technique [2]. Prior to the final surgical intervention, a quantity of radio-labeled colloid is injected into the breast, usually in the region around the tumor. The distribution of the radiotracer is visualized by a gamma camera image, revealing the lymph nodes that are draining the breast tissue with the tumor. These local lymph nodes, usually numbering between one and three, are called the sentinel nodes. The surgeon identifies the sentinel node with a small Geiger probe and removes the nodes for investigation by the pathologist. This is done either perioperatively or following the primary operation. If the nodes show histological metastatic deposits, an axillary dissection is performed [3].

The sensitivity and specificity of the SNL technique is generally high. However, the technique is not feasible for all breast cancer patients, and a non-invasive tool for identification of malignant lymph nodes would be of particular interest for non-SNL candidates. Suggested contra-indications for SNL are multifocal or multicentric lesions, previous axillary surgery, previous irradiation therapy, and neo-adjuvant chemotherapy [4–6], although large investigations regarding these contraindications are still needed.

Conventional imaging cannot accurately assess axillary lymph node involvement. Different imaging approaches have been evaluated for the use in axillary staging, and currently computer tomography and ultrasonography are the most widely used. However, no imaging modality has yet shown satisfactory sensitivity or specificity in this respect. Factors such as size and shape have been used to discriminate between malignant and benign lymph nodes, but these evaluation criteria have their obvious limitations.

A newer approach using dynamic contrast-enhanced magnetic resonance seems promising for evaluation of primary tumors for breast cancer patients after neo-adjuvant chemotheraphy and has been evaluated as a surrogate marker for prediction of nodal status [7]. This indirect assessment of nodal involvement may however be associated with an unsatisfactory high false-negative rate.

PLOS ONE | www.plosone.org 1 January 2013 | Volume 8 | Issue 1 | e54047
The diagnostic value of F-18 -Fluorodeoxy-glucose-Positron Emission Tomography (F-18-FDG-PET) with or without diagnosti
cutaneous CT has also been evaluated as a tool for preoperative
axillary staging [8,9]. But again, a sensitivity around 60-70%
seems unsatisfactory compared to SNL verified by histopatholog-
ical examination.

Due to the high prognostic implication of axillary lymph node
involvement, it is of paramount importance to identify a possible
spread of disease for proper staging and thereby choice of
treatment strategy. Especially false negative cases should be
minimized for improved prognosis but also false positive cases,
since removal of the whole axilla is associated with significant
morbidity such as lymphedema in the affected arm and limitations
of shoulder movement [10,11]. Thus, the development of a safe
pre-operative, non-invasive imaging technique to identify lymph
node metastases would be of tremendous value. Such an imaging
method could spare the patient for axillary surgery if negative,
and if positive, the primary tumor and the affected nodes could be
removed during the same operation and proper treatment initiated
faster.

Tiny density variations in human tissue are difficult or
impossible to detect with conventional X-ray imaging, but they
can be visualized by grating-based phase-contrast X-ray tomog-
raphy [12–18]. Due to the wave-optical interaction of x-rays with
matter, the contrast available with phase-contrast imaging is much
higher than standard X-ray absorption imaging. Hence, the
density variations caused by invasive cancer can be visualized.
Here we report high-contrast biomedical phase-contrast imaging
using synchrotron radiation [19–21] applied to human lymph
nodes. The purpose of this study was, in a blinded manner, to
investigate whether malignancy could be revealed by non-invasive
x-ray phase-contrast tomography in lymph nodes from breast
cancer patients.

Materials and Methods

Samples
Written informed consent was obtained from all participants
and the study was approved by the regional scientific ethical
committee. Seventeen formalin-fixed, paraffin-embedded axillary
lymph nodes were used for the study, all from axillary dissection
specimens from women with invasive ductal breast carcinoma. All
lymph nodes were weighed, measured on the longest diameter and
cut in half prior to formalin-fixation. One half of the formalin
fixed-paraffin-embedded lymph node was used for the study and
the other for routine histological examination.

Each sample was paraffin embedded in a small plastic tray
following the standard protocol for histology slicing. Haematoxylin
and cosin staining (H&E-staining) was performed according to
routine procedures on 10 μm sections from all samples on the
experimental half of the lymph node to verify the diagnosis. In
addition, prior to sectioning and staining, each sample was imaged
using phase-contrast tomography. For x-ray phase-contrast
imaging the paraffin embedded lymph nodes were removed from
their trays and brought to the synchrotron radiation facility.

Phase-contrast Micro-tomography

The x-ray imaging measurements were carried out at the ID19
beamline at the European Synchrotron Radiation Facility (ESRF),
in Grenoble, France [22]. A grating interferometer was placed 150
meters from the wiggler source (see Figure 1). The principle and
set-up of the x-ray grating interferometer has previously been
described in detail [12,23–27]. In this experiment we have used a
monochromatic x-ray beam at 23 keV. The Si phase grating
(G1, π-phase shifting) was placed after the sample, had period of
4.785 μm and a height of 29.5 μm and had been produced using
photolithography and wet chemical etching [27]. The Au
absorption grating (G2) was placed in front of the detector, had
period of 2.400 μm and a height of 30 μm. It had been produced
using soft X-ray lithography [28]. A FReLoN CCD detector with
an effective pixel size of 14.9×14.9 μm² with 1024×1024 pixels
was used. The field of view was limited horizontally by the number
of pixels of the detector, and vertically by the x-ray beam size; this
resulted in a field of 15.3 mm width and 13.7 mm height.

For each tomographic dataset four phase step projections with
an exposure time of 0.5 seconds each were collected for 701 angles
evenly distributed over 360 degrees. This resulted in a total net
exposure time of 24 minutes. Due to the large field-of-view four
samples could be measured simultaneously. The data was
reconstructed using a Hilbert-filter-based phase-contrast filtered
back-projection algorithm [29]. A phase unwrapping procedure
was applied prior to reconstruction to suppress cupping artifacts.
For each sample the dataset included (depending on the size of the
sample) 100–225 adjacent 14.9-μm-thick slices, thus providing
a full 3D image of the sample.

Data Analysis and Statistics

Each image was converted to DICOM format and imported
into the Inveon Software (Siemens Medical Solutions, Inc.,
Knoxville, TN, USA) for analysis by two experts in Medical
Imaging. The study was blinded and retrospective.

Since the technique was new and the images unlike prior
absorption x-ray images, the experts who analyzed the scans first
looked at a test set of three images and set their diagnosis, then
they were given the correct diagnosis before completing the rest of
the image analysis. This was done in order to know which features
to look for in the benign and malignant lymph nodes respectively.
The reference for metastatic disease was histopathology diagnosis
set by a pathologist who was blinded to the x-ray phase-contrast
results.

For comparison between groups for diameter and weight an
independent-samples t-test was used. The statistical analyses were
calculated using SPSS version 17.0 (SPSS Inc, Chicago, IL).
P<0.05 was considered significant.

Figure 1. Experimental setup. Not to scale. The sample is placed in
front of the interferometer as close as possible to the first grating. The
distance between the two x-ray optical transmission gratings, G1 and
G2 is dictated by the fractional Talbot order. The detector is placed
immediately after G2. The phase-contrast images are collected for each
rotation angle Ω by scanning G1, along the transverse direction in four
steps.

Results

Twenty-three samples were visualized by phase-contrast microtomography. Due to technical challenges, as no experimental protocol was available before the experiment, some samples were excluded before the final image analysis. All samples were embedded in paraffin but they were removed from their trays in a way that was not optimized for the imaging procedure. For optimal phase-contrast imaging the sample embedding should be of convex shape and free of cracks. Establishment of this protocol lead to failed sample handling resulting in poor image quality of 6 samples. Therefore, seventeen lymph nodes from 10 patients were included in the final analysis. The age range of the 10 patients was 37–83 years (median age 60 years).

The 17 included lymph nodes were collected from 10 patients with clinical suspiciousness of nodal involvement and all underwent complete axillary resection. Of these 10 patients, 1 had no metastasis in the resected axillary specimen, 3 had 1–3 affected nodes, 3 had 4–6 affected nodes and 3 had more than 6 affected nodes.

Of the 17 included axillary lymph nodes, histological examination confirmed that n = 10 were infiltrated with invasive ductal breast carcinoma and n = 7 were without metastatic deposits. All lymph nodes with metastatic deposits that were included in the study had macro-metastases. The 10 lymph nodes with cancer infiltration had a weight of $(4.1 \pm 3.3)$ g (mean ± standard deviation), and a diameter of $(24 \pm 6.8)$ mm. The lymph nodes without malignancy had a weight of $(0.6 \pm 0.4)$ g, and a diameter of

Figure 2. Phase-contrast tomography images of lymph nodes. Without (upper panels) and with (lower panels) metastatic deposits from patients diagnosed with invasive ductal breast carcinoma. The lymphoid follicles can easily be distinguished in the images of the benign lymph nodes. In the lower panels the invasive edge (arrows) clearly mark the border between the metastatic majority (lighter) part of the lymph node and the smaller part of the node with intact normal cells (darker). doi:10.1371/journal.pone.0054047.g002
(14±4.3) mm. The malignant lymph nodes had a significantly higher weight and larger diameter than the non-malignant lymph nodes (p = 0.015 and p = 0.005, respectively).

All of the 10 metastatic lymph nodes had a longest diameter that was above 10 mm, which is the criterion for considering the lymph node suspicious of malignancy on CT. Two lymph nodes were however close to 10 mm with the longest diameter of 12 and 13 mm respectively, which could be within the range of measurement inconsistence on CT images, and the lymph nodes could be considered non-malignant on conventional CT or not be detected at all.

The raw data and image reconstruction was carried out by experts in x-ray physics. The final images were analyzed by two experts in Nuclear Medicine who analyzed the images had 1 false positive result and no false negative results. The false positive sample was however different for the two experts. Thus, the inter-observer agreement was 88% (15 of 17 lymph nodes) for classification of the lymph nodes as malignant or benign. The diagnostic sensitivity of the image analysis was 100% and the specificity was 87%. The positive predictive value was 91% and the negative predictive value was 100%. The features that were characteristic of the benign lymph nodes, were an ordered structure with clearly visible lymphoid follicles (see figure 2 upper panels), whereas the malignant lymph nodes had features such as calcification, changed morphology, and a general disorganized appearance. From the example in figure 2 (lower panels) the border between the cancer-infiltrated and the non-infiltrated part of the lymph node can be seen with a clear gray level difference (cancer infiltration lighter) due to the changed density of the tissue caused by the cancer infiltration.

**Discussion**

The axillary status is one of the most important prognostic factors for breast cancer patients. Therefore, correct assessment of nodal involvement is of utmost importance, and the sentinel node technique has evolved as a mandatory part in the evaluation and staging of breast cancer patients. However, the SNL is not always indicated, e.g. for patients undergoing neo-adjuvant chemotherapy, and other approaches for axillary assessment are warranted.

Using x-ray phase-contrast tomography we demonstrate here a high sensitivity (100%) as well as specificity (86%), positive predictive value (91%) and negative predictive value (100%) with no false-negative cases. In the non-metastatic lesions the lymphoid follicles were clearly visible whereas the metastatic lesions had lost this ordered morphology. This change in morphological characteristics was clearly visible upon image analysis. This is the first time that a non-invasive imaging modality has demonstrated the ability to visually identify morphological differences between malignant and benign lymph nodes. Accordingly, x-ray phase-contrast micro-tomography gives histological information in a non-invasive manner which allows for discrimination between benign and malignant lymph nodes.

In this study, micro-metastases were not analyzed, and the detection limit for identification of metastatic deposits in lymph nodes is so far not known for this imaging approach. However, given the high morphological information achievable with x-ray phase-contrast tomography, we believe that this technique is more powerful than imaging approaches otherwise available. In addition, it is questionable what the prognostic implication of micro-metastases is. It is known that intra-operative false-negative cases are often micro-metastases or isolated tumor cells. Two studies investigated the role of intra-operative false-negative cases. In these studies, 75% of the false-negative cases were micro-metastases or isolated tumor cells. There was no significant difference in recurrence rate between patients with true-negative SNL and patients with intra-operative false-negative SNL not undergoing axillary lymph node dissection [30,31]. Thus, from the results of these studies it seems possible that the clinical significance of micro-metastases is limited.

The non-invasive diagnostic method proposed here, based upon x-ray phase-contrast imaging, can be used for identification of metastatic deposits in lymph nodes. Once developed into a clinical routine this x-ray phase-contrast imaging methodology could have a great impact on diagnosis and treatment in patients with breast cancer. The present sentinel node technique might then be replaced by a non-invasive preoperative x-ray phase-contrast evaluation of lymph node involvement in patients with breast cancer, and surgical intervention could be reduced to one operation, and perhaps more importantly, proper choice of treatment could be initiated faster.

The method of grating-based x-ray phase-contrast imaging has already been demonstrated using standard laboratory x-ray sources [16–17,32–36], making its use in the clinic feasible. We believe that the images presented here will constitute the next step towards a new concept for imaging cancer and possibly other diseases. The implementation of phase-contrast x-ray imaging in a clinical environment could be envisioned as a high-resolution micro-CT for surgically removed tissue samples ex-vivo as an alternative to histology, or as an in-vivo full body CT.

In conclusion, we describe a new method using phase-contrast tomography that has a high sensitivity and specificity for non-invasive detection of lymph node metastases. The method has a high clinical potential and in the future may lead to non-invasive axillary staging of breast cancer patients.
