Abstract

Burnout syndrome (BOS) is a work-related constellation of symptoms characterized by emotional exhaustion, depersonalization, and personal accomplishment. A cross-sectional survey was performed to study the prevalence of BOS among a randomly selected sample of 280 Italian Red Cross volunteers. A socio-demographic questionnaire and the Maslach Burnout Inventory (MBI)-HSS were used to collect data. 241 volunteers participated (response rate: 86.1%). A significant proportion of the workers had BOS subscale scores in the highest tertile: emotional exhaustion 8.0%, depersonalization 35.9% and perceived lack of accomplishment 23.5%, respectively.

Volunteers in emergency care reported higher levels of emotional exhaustion (p = 0.004) and depersonalization (p = 0.001), and lower level of personal accomplishment (p = 0.042) than volunteers engaged in non-healthcare social and administrative duties. These findings support the opportunity of a set of administrative, organizational and individual preventive interventions for emergency volunteers’ mental health.

Key words: Burnout syndrome; emergency care; mental health; Red Cross; volunteers
Prevalence of burnout syndrome among Italian volunteers of the Red Cross: A cross-sectional study

Introduction

Burnout syndrome (BOS) is a work-related condition that has been conceptualized as resulting from chronic workplace stress that has not been successfully managed\(^1\), which occurs in professionals frequently and/or severely exposed to crises and high-pressure situations, shift and overnight work, erratic work schedule, and stressful workloads\(^2\)\(^5\), mainly including healthcare workers, and helping professions (i.e. as policemen and firefighters)\(^6\)\(^\text{-}11\)). Since 2001, the three dimensions of BOS have been described as “exhaustion” (i.e. the feeling of not being able to offer any more of oneself at work), “cynicism” (i.e. a distant attitude towards work, clients and/or colleagues), and “inefficacy” (i.e. the feeling of not performing tasks adequately)\(^7\)\(^\text{-}12\)\(^\text{,}13\)).

BOS has been especially studied among healthcare professionals\(^14\)\(^\text{-}18\)), and available figures suggest that, even before the ongoing COVID-19 pandemic, it may affect more than half of practising physicians in the USA\(^19\)). Because of its potential impact on healthcare services, including poorer quality of care, professional mistakes, absenteeism, intention to give up the profession, and abandonment, physician burnout has been defined as a “global crisis”\(^19\)).

Among the helping professions, first aid volunteers (FAVs) are a category of workers often overlooked with respect to the risk of developing burnout. In particular, those employed in ambulance service have a continuous contact with ill or suffering people, with resulting risk of developing “compassion fatigue”, i.e. a condition characterized by emotional and physical exhaustion leading to a diminished ability to empathize or feel compassion for others\(^4\)\(^\text{-}5\)).
FAVs face health and safety risks in order to assist in medical emergencies, motor vehicle incidents, building and wild-land fires, hazardous material spills, crimes and public disturbances, search and rescue\textsuperscript{20,21}). Moreover, they are among the first responders to basic needs in case of natural and man-made disasters, in support of population that needs clean water, shelter, food assistance and protection. Alongside military health care workers, public health service workers, and state, local, and volunteers, FAVs therefore play an important role in protecting citizens in the aftermath of disasters, being not spared by a wide range of mental health consequences such as post-traumatic stress disorders (PTSD), depression, anxiety, acute stress, and particularly BOS\textsuperscript{22}). Indeed, FAVs are not spared by the rising threat of workplace violence, a significant effector eliciting job burnout\textsuperscript{23-29}). Among FAVs, ambulance workers are particularly exposed to verbal/psychological violence during their duties, and this risk factor has been associated with high level of burnout \textsuperscript{30,31)}, with a resulting increased risk for critical incidents \textsuperscript{32-33)}. 

Even though BOS has been extensively characterized in emergency healthcare personnel\textsuperscript{34-42)}, research on FAVs is relatively scarce, and evidence is somewhat conflicting, particularly for Italian personnel. For instance, a study on a small sample of Italian Red Cross volunteers did not list BOS as a major problem\textsuperscript{43)}, and two Italian studies, including a little group of ambulance driver-rescuers, reported inconsistent findings\textsuperscript{44,45)}. Eventually, another study on a larger but regional-based sample (i.e., 2,361 FAVs from the Sicily Region alone) of ambulance driver-rescuers found a BOS prevalence of 29.8\%\textsuperscript{46}). 

The aim of this research was therefore to study the prevalence of BOS in FAVs of the Italian Red Cross, then comparing the levels of the three BOS sub-dimensions between
FAVs engaged in social activities and those engaged in emergency care in order to identify their potential predictors.
Subject and Methods

Study design and setting

The present cross-sectional survey was performed in April-May 2019 among volunteer members of ten local committees of the Red Cross in Salerno, Campania, Southern Italy, which is the second most populous city in Campania region (Total area 4,954.16 km²; with 1,092,779 inhabitants according to 2019 census), with a total of around 2,500 FAVs active at the time of the survey (2019).

The Italian Red Cross (in Italian: Croce Rossa Italiana; CRI) is among the original founding members of the International Committee of the Red Cross in 1919 and includes around 11,590 no profit associations for over 400,000 volunteers\(^4\)). Service as FAVs is deeply grounded within the Italian healthcare system. In facts, while the International Committee of the Red Cross mainly ensures humanitarian protection and assistance for victims of war and other situations of violence, CRI alongside other organizations for voluntary assistance (in Italian: Pubblica Assistenza or Misericordia), supports the Italian National Health Service also for daily medical emergencies, including ambulance services and first aid activities.

Despite their non-medical status, FAVs of the Italian Red Cross are medically trained personnel. Their training path is known as MTAR (Medical Transport and Ambulance Rescue) with the following basic requirements: a) being ≥ 18-year-old; b) having completed a training course including Cardiopulmonary resuscitation (CPR) and First Aid rules; c) having received a formal formation course on health and safety in the workplace according to Italian National Law (i.e. Legislative Decree No. 81 of April 9\(^{th}\), 2008); and d) fulfilling psycho-physical requirements for ambulance service, as assessed by a special commission of medical and psychologist specialists. Formal and professional requirements of FAVs are periodically updated, as qualification as FAVs
requires a periodical retraining. Even though FAVs do not receive a formal salary from CRI and/or Italian National Health Service, they have to guarantee from 2 to 20 shifts of work per month. Even though personal working shifts depend on the type of service provided, they usually face long-hours and tiring shift work\textsuperscript{48).}

\textit{Study population, sampling and data collection}

A total of 280 FAVs were randomly selected from all Volunteers of the CRI committee of Salerno. Inclusion criteria were: having a civilian background; performing either administrative or healthcare assistance tasks; having accomplished initial qualification.

\textit{Ethical aspects}

The study protocol was approved by the Local Board of the Organism with internal protocol n.146/29.02.12. Moreover, an informed consent from each study subject to participate in the study was obtained before the start of work with assurance of confidentiality and anonymity of the data, according to ethical principles for medical research involving human subjects\textsuperscript{49}. Subjects were invited personally by the investigator (psychologist) and they were asked to participate voluntarily with a full right to withdraw from the study. Our study was conducted in accordance with the ethical standards of the Declaration of Helsinki (2008).

\textit{Study instruments}

An \textit{ad hoc} descriptive questionnaire form was prepared by the researchers regarding socio-demographic and occupational characteristics. Sociodemographic data (age, sex and education) and information on employment situation, including years of experience, type of work (driving ambulance with rescue tasks \textit{vs} ordinary jobs) was collected.

To survey burnout syndrome, the Maslach Burnout Inventory (MBI)-HHS was used. MBI, which is the most commonly used tool to diagnose burnout, was developed by
Maslach and Jackson (1981) and adapted in Italy by Sirigatti and Stefanile to healthcare workers. With this inventory, the burnout situation was assessed through three sub-dimensions: Depersonalization (DP); Emotional Exhaustion (EE), and Personal Accomplishment (PA). The MBI is a 22-item self-completed questionnaire with the following subscales: ‘EE’ (9 items) measures feelings of being emotionally overextended and exhausted by one’s work. “DP” (5 items) measures an unfeeling and impersonal response toward recipients of one’s service, care treatment, or instruction. “PA” (8 items) measures feelings of competence and successful achievement in one’s work (Mind Garden.com). All given answers are related to a 7-point Likert scale ranging from 0 (never) to 6 (every day) to express how frequently a person experiences the dimensions of burnout. These subscales are considered “high,” “average,” or “low” according to predetermined cut-off scores based on normative data. Scores are considered “high” if they are in the upper third of the normative distribution, “average” if they are in the middle one, “low” if they are in the lower third. Each subscale score is separately calculated; higher mean scores for DP and EE subscales and lower mean scores on the PA subscale correspond to a higher degree of burnout. The Italian validation of the questionnaire established the following ranges: high EE ≥24, DP ≥9, PA ≥37; average EE=15–23, DP=4–8, PA=30–36; low EE ≤14, DP ≤3, PA ≤29. The Italian normative sample of 748 Italians working in the healthcare professions gave EE=20.18±11.29; DP=7.03±5.9; PA=32.52±8.66.

In literature, there is no accepted standard definition for measuring burnout as a binary variable and the ideal approach is to use the individual domain scores as continuous data. For this reason, in this study we dichotomized the scores in the lower third and in the high/middle third, where a manifestation of burnout to be present in a respondent
if the specific MBI subscore for that manifestation would have placed the respondent into the high/middle category.

Cronbach’s α coefficient was used to test the internal consistency reliability for each MBI subscale. Authors calculated the Cronbach’s alpha coefficients of the sub-scales as 0.83 for EE, 0.72 for PA and 0.65 for DP.

**Statistical analyses**

A descriptive analysis was undertaken to determine the characteristics of the study participants. Continuous data were reported as a mean or standard deviation, whereas categorial data were reported as a number or percentage. Univariate comparisons between participants performing emergency duties vs. social/administrative ones were initially performed by means of chi squared test (with Yates correction) for dichotomous variables, while continuous variables were assessed by means of Student’s t test for unpaired data. Similarly, for each dimensions of burnout the differences in sociodemographic characteristics were initially assessed through by means of Student’s t tests (with Bonferroni’s correction for multiple comparisons). A two-ways Analysis of Variance (ANOVA) including both sociodemographic characteristics and work-related characteristics was then modeled for the three BOS dimensions, each one separately.

Eventually, in order to assess the impact of sociodemographic and work-related characteristics on BOS dimensions, a multiple linear regression was then modeled, calculating correspondent B regression coefficients with 95% confidence interval (CI) and the Nagelkerke’s R² for the outcome variable represented by the specific dimensions of burnout (i.e., EE, DP, PA). We opted for an “a priori” model that included as independent variables all factors assessed in univariate analysis (i.e., age, sex, seniority as emergency professional, education achievement). Two distinctive
models were calculated, including all the sample as a whole, and only participants performing emergency duties.

Analyses were performed by means of IBM SPSS Statistics, version 25.0 (IBM Corp., Armonk, N.Y., USA) R (version 3.6.1; R Core Team, 2017. R: A language and environment for statistical computing. R Foundation for Statistical Computing, Vienna, Austria. URL https://www.R-project.org/), and RStudio (version 1.2.5019) software by means of car package (version 3.0-10). Significance level was set at $p < 0.05$ for all calculations.

**Results**

The final study sample included a total of 241 participants (participation rate of 86.1%; Figure 1), with a mean age of $36.67 \pm 14.14$ years (actual range 18 to 73), and 57.7% of them were female.

*Please, insert Figure 1 here*

As shown in Table 1, 162 out of 241 participants (i.e., 67.2%) had emergency duties (i.e., ambulance drivers and first aid responders). Nearly half of them (49.6%) reported more than 6 years of seniority. Remaining participants (32.8%) engaged in social and administrative jobs were significantly younger (i.e., $27.46 \pm 12.21$ years of age vs. $36.67 \pm 14.14$, $p < 0.001$), and exhibited a generally lower educational achievement (i.e., 6.3% with a university-level degree compared to 15.4% among personnel performing emergency duties, $p = 0.041$).

*Please, insert Table 1 here*

Overall, estimates for EE, FP and PA were $5.29 \pm 7.06$, $3.51 \pm 4.16$, and $36.37 \pm 8.96$, respectively, with 11 participants (4.6%) having high likeliness of BOS status, all of them from ambulance personnel ($p = 0.041$). Corresponding subscale thresholds for medium-high burnout, subscale prevalence values were 8.7% for EE, 37.6% for DP, and
40.2% for PA. Ambulance personnel exhibited higher values of EE (6.04 ± 8.02 vs. 3.76 ± 4.11, p = 0.004), and DP (3.93 ± 4.43 vs. 2.66 ± 3.39, p = 0.015), while the PA dimension scored lower values in this subset compared to administrative / social personnel (34.73 ± 8.32 vs. 37.16 ±9.17, p = 0.048).

Please, insert Table 2 here

Comparisons of the sub-dimensions scores (Table 2) enlightened higher EE estimates in people having longer service in emergency settings (8.15 ± 10.56 vs. 4.46 ± 5.78, p = 0.033) and reporting higher education level (10.37 ± 1.89 vs. 4.79 ± 6.33, p = 0.045). In both cases, when focusing on FAVs performing emergency duties, the differences were not significant (p = 0.083, and p = 0.077, respectively).

DP was higher in women (3.96 ± 4.56 vs. 2.90 ± 46, p = 0.41), and the difference remained appreciable in the subset of participants with emergency duties (4.56 ± 4.93 vs. 3.07 ± 3.50, p = 0.025), while its was not among participants performing administrative/social jobs (2.74 ± 3.42 vs. 2.55 ± 3.40, p = 0.804), and also the ANOVA ruled out a significant difference (p = 0.253).

Again, length of service was associated with higher score among people performing emergency duties for more than 10 years when compared to other participants (5.37 ± 5.15 vs. 3.08 ± 3.77, p = 0.006), and the difference remained significant in the subset of emergency workers (p = 0.020). Eventually, higher PA were scored among FAVs of female gender (38.15 ± 8.43 vs. 35.06 ± 9.13, p = 0.007), and particularly when focusing on emergency workers (39.67 ± 7.94 vs. 35.30 ± 9.60, p = 0.002), while the correspondent score for participants performing administrative and/or social jobs was quite similar (34.97 ± 8.67 vs. 34.57 ± 8.16, p = 0.835), and the ANOVA eventually disclosed a significant difference when taking in account both gender and qualification (p = 0.105). Interestingly enough, PA estimates were also higher in older participants (>
35 years of age at the time of the survey; i.e. 37.88 ± 9.01 vs. 35.29 ± 8.79, p = 0.027), and particularly among participants performing administrative/social jobs (38.21 ± 6.60 vs. 33.63 ± 8.54, p = 0.036), while in the subset of emergency workers the estimates were somewhat similar (37.70 ± 9.52 in older age groups compared to 36.52 ± 8.82, p = 0.375), and ANOVA reported no significant differences in-between the subsets (p = 0.226).

Please insert Table 3 here

In regression analysis (Table 3), female gender was acknowledged as the only negative predictor for the BOS dimension of PA (B -0.250, 95%CI -0.453 to -0.047, p = 0.016 for the sample as a whole; B -0.303, 95%CI -0.566 to -0.040, p = 0.024). In facts, all analysis were characterized by very low values of Nagelkerker’s $R^2$, the statistical measure that represents the proportion of the variance for an outcome variable that's explained by independent variables, with an estimate of 0.013, 0.034, and 0.026 for EE, DP and PA, respectively, i.e. only 1.3%, 3.4% and 2.6% of the observed variation can be explained by the model's inputs.

Discussion

Our study shows that the mental problems that characterize BOS are not absent in volunteers. In our cross-sectional study, significant differences were found by gender, i.e., higher levels of EE and DP in females, age and level of experience. Length of service with more than 10 years was also associated with higher levels of EE and DP in the overall sample of Red Cross volunteers.

More precisely, emotional exhaustion and depersonalization were higher, and personal accomplishment lower, in FAVs engaged in emergency duties than among volunteers engaged in social and administrative activities.
In multivariate analysis, length of service was confirmed as the only predictor of EE and DP in the sample considered as a whole, but not in the sub-sample of emergency volunteers.

The higher levels of BOS among volunteers performing emergency assistance, confirm the existing association between emergency jobs and BOS previously described in literature\textsuperscript{52, 53}. A qualitative study on 14 professionals and 11 volunteer ambulance rescuers of the Italian Red Cross showed frequent exposure to highly challenging situations and higher anxiety levels among volunteers\textsuperscript{54}.

However, in our study the prevalence of burnout and sub-dimensions scores was rather low if compared to levels of BOS reported by a meta-analysis showing that 40% emergency medicine physicians experience high levels of emotional exhaustion and depersonalization\textsuperscript{55}.

In facts, FAVs who support emergency healthcare professionals are requested to protect and assist the patients and/or driving the ambulance \textsuperscript{56}, and all these duties could obviously lead to burnout and other mental health outcomes, even if no universal consent has been reached on the evaluation of the susceptibility to burnout in social and welfare volunteers\textsuperscript{57}, and particularly on its dimensions. For instance, Gabassi et al.\textsuperscript{58}, have focused on the differences in susceptibility to burnout between volunteers and professional operators, and volunteers scored lower median ratings of exhaustion and reduced personal accomplishment than professionals, probably due to their job motivation. On the contrary, a literature review on volunteers from the healthcare settings hinted that both volunteers and regular staff are usually subject to high levels of depersonalization, but FAVs apparently do not differ from the norm in susceptibility to emotional exhaustion and self-realization\textsuperscript{59, 60}. On the contrary, according to Vecina et al.\textsuperscript{61} and Ripamonti\textsuperscript{57}, carrying on a volunteering activity for a long time can trigger
high levels of emotional exhaustion which, according to Maslach’s (1982) model\(^6\), often is the first step in the process leading to burnout syndrome. Not coincidentally, also in our study, volunteering in healthcare assistance was associated with higher level of both emotional exhaustion and depersonalization than volunteering in administrative duties, i.e., activities that are only marginally associated with emotional triggers of BOS. Higher level of DP than EE in our study, confirms the model by Golembiewsky et al.\(^62\), in which depersonalization leads to a reduction in self-satisfaction and finally to emotional exhaustion.

Pardess has highlighted the fundamental role of an adequate formation of volunteers in preventing stress and burnout\(^63\). Healthcare staff are at high risk of mental health problems, and this could affect also volunteers employed in emergency activities\(^17, 53, 64-67\). Therefore, healthcare managers need to proactively take steps to protect their mental wellbeing\(^68\). Burnout, indeed, has been associated with deleterious effects on both healthcare workers and the quality of their work\(^69\). However, very little attention has been given on the critical issue of volunteer burnout. When burnout affects healthcare workers, both their well-being and care of patients may be at risk\(^70\).

Furthermore, emotional exhaustion in emergency responders has been linked to a significant increased suicide risk\(^71\), secondary traumatic stress\(^72\) and compassion fatigue, which results from exposure to a traumatized individual and is described as the convergence of secondary traumatic stress (STS) and cumulative burnout (BO)\(^73\).

Likewise, volunteers employed in emergency should be considered in the same way and, therefore, they should require preventive measures through mandatory occupational health and safety regulations, including tailored interventions such as health surveillance and specific training and formation on the basis of type of job and length of service. The prevalence of BOS volunteers in this study, which was lower than other
studies, could be in part explained by the preventive work effectively performed by the Red Cross health service department by permanent training services direct to volunteers and provided by occupational health physicians and psychologists. In Italy, the Red Cross organization has a working team of volunteers and psychological experts who provide volunteers with support programmes in coping and resilience within the framework of the psychology of emergency. Therefore, regular health surveillance programmes on workers employed at Italian Red Cross could have maintained sufficient level of mental well-being among staff and volunteers, as shown in our sample.\(^{74}\)

Moreover, nonstandard job motivation in volunteers in perceiving their work as a “vocation”, could be a protective factor against BOS and should be taken into account.\(^{62}\)

This lack of evidence is particularly frustrating when applied the Italian settings, where formal volunteering in healthcare is a nation-wide phenomenon since the end of 19th century, and a large number of lay volunteers carry out their activity for social welfare and healthcare services, either in hospital and community settings.

This study has some limitations. The cross-sectional design of the research prevented us from infer any causal relationship between ambulance volunteering work and burnout syndrome. Other studies have also considered some potential sources of burnout in emergency ambulance workers, such as personality characteristics\(^{75}\) and exposure to violence\(^{30}\), that we have not included in this research. In addition, only a few of socio-demographic characteristics were included in our prediction model.

However, there are also some strengths in this work, that is one of the few carried out among volunteers of the Red Cross. Therefore, we believe that our study could pave the way to further and in-depth research, that should take into consideration the moderating role on the relationship between verbal/physical violence, job stressors and BOS played by the organization and context of volunteering\(^{76}\), which are often neglected, and the
important role of traits of personality\textsuperscript{77}, as well as of self-efficacy\textsuperscript{78,79} and self-esteem in the onset of BOS, which is prominent in emergency healthcare as much as in non-healthcare volunteers as well.

Conclusion

In conclusion, our study found that volunteers of the Red Cross engaged in emergency care reported higher levels of emotional exhaustion and depersonalization and lower level of personal accomplishment than volunteers from the same organization who are engaged in non-healthcare assistance activities. This shows the need to consider the risk of BOS in non-healthcare volunteers employed in healthcare activities and the need to protect this category of helping profession through work organization interventions on the categories at highest risk (particularly on women and veterans), occupational health surveillance programmes and psychological and debriefing emergency services.

### Table 1. Characteristics of 241 First Aid Volunteers (FAV) participating into the study on burnout syndrome (Salerno Province, Southern Italy, 2019)

| Variables                        | Total Sample (No.241, %) | Activities performed as FAV | P value |
|----------------------------------|--------------------------|----------------------------|---------|
|                                  |                           | Emergency duties           | Administrative / Social jobs |
|                                  |                           | (No.162, %)                | (No.79, %) |
| Gender                           |                          |                            |         |
| Males                            | 102, 42.3%               | 69, 42.6%                  | 33, 41.8% | 0.904 |
| Females                          | 139, 57.7%               | 93, 57.4%                  | 46, 58.2% |
| Age group                        |                          |                            |         |
| 18 – 35 years                    | 141, 58.5%               | 81, 50.0%                  | 0,   -   | < 0.001 |
| 35 years of more                 | 100, 41.5%               | 81, 50.0%                  | 19, 24.1% |
| Educational achievement          |                          |                            |         |
| Primary school (i.e. < 9 years of formal education) | 58, 24.1% | 33, 20.4% | 25, 31.6% | 0.041 |
| High school (i.e. 9 to 14 years of formal education) | 153, 63.5% | 104, 64.2% | 49, 62.0% |
| University (i.e. > 14 years of formal education) | 30, 12.4% | 25, 15.4% | 5, 6.3% |
| Seniority in emergence duties   |                          |                            |         |
| < 1 year                         | 79, 32.8%                | 0, -                       | 79, 100% | < 0.001 |
| 1-5 years                        | 82, 34.0%                | 82, 50.6%                  | N/A     |
| 6-10 years                       | 33, 13.7%                | 33, 20.4%                  | N/A     |
| 11-15 years                      | 17, 7.1%                 | 17, 10.5%                  | N/A     |
| Over 15 years                    | 30, 12.4%                | 30, 18.5%                  | N/A     |
| Burnout sub-dimensions           |                          |                            |         |
| Emotional exhaustion (EE)        | 5.29 ± 7.06              | 6.04 ± 8.02                | 3.76 ± 4.11 | 0.004 |
| Emotional exhaustion (EE), Medium-high level vs. low level | 21, 8.7% | 19, 11.7% | 2, 2.5% | 0.033 |
| Depersonalization (DP)           | 3.51 ± 4.16              | 3.93 ± 4.43                | 2.66 ± 3.39 | 0.015 |
| Depersonalization (DP), Medium-high level vs. low level | 93, 38.6% | 71, 43.8% | 22, 27.8% | 0.025 |
| Personal accomplishment (PA)     | 36.37 ± 8.96             | 34.73 ± 8.32               | 37.16 ± 9.17 | 0.048 |
| Personal accomplishment (PA), Medium-high level vs. low level | 97, 40.2% | 58, 35.8% | 39, 49.4% | 0.061 |
| Likeliness of Burnout            | 11, 4.6%                 | 11, 6.8%                   | 0, -    | 0.041  |
Table 2. Comparison of the three dimensions of burnout syndrome among 241 first aid volunteers (FAVs), from Salerno province (Campania, Southern Italy; 2019). Comparisons by gender, age group (18-35 years vs. > 35 years), length of service (≤ 10 years vs. > 10 years), educational level (undergraduate vs. graduate) were initially performed by means of Student’s t test for unpaired data. A two-way ANOVA was then modeled taking in account the qualification (i.e. FAVs performing emergency duties vs. FAVs performing administrative/social jobs).

|                          | Emotional exhaustion | Depersonalization | Personal accomplishment |
|--------------------------|----------------------|-------------------|------------------------|
|                          | Total sample (No. 241) | Emergency duties (No. 162) | Admin. / Social jobs (No.79) | Total sample (No. 241) | Emergency duties (No. 162) | Admin. / Social jobs (No.79) | Total sample (No. 241) | Emergency duties (No. 162) | Admin. / Social jobs (No.79) |
| **Gender**               |                      |                   |                        |                      |                   |                        |                      |                   |                        |
| Women                    | 5.84 ± 7.99          | 6.87 ± 9.08       | 3.78 ± 4.56            | 3.96 ± 4.56          | 4.57 ± 4.93       | 2.74 ± 3.42            | 35.06 ± 9.13          | 35.30 ± 9.60          | 34.57 ± 8.16            |

Table 3. Predictors of burnout syndrome (BOS) among 241 First Aid Volunteers (FAVs) participating into the survey. Two distinctive models were assessed, initially by assessing the sample as a whole (No. 241), and then by analyzing the subset of FAV performing emergency service (i.e. “emergency workers”). Note: EE = Emotional exhaustion; DP = depersonalization; PA = personal achievement.

| Dimension of BOS | All participants | Subset of Emergency workers |
|------------------|------------------|-----------------------------|
|                  | Factor           | B  | 95%CI | P value | B  | 95%CI | P value |
| EE               | (Constant)       | 0.913 | 0.624; 1.203 | < 0.001 | 0.936 | 0.457; 1.415 | < 0.001 |
