Mechanisms of Asthma and Implications for Its Prevention and Treatment: A Personal Journey

Stephen T Holgate*

Faculty of Medicine University of Southampton, UK

My research career has focused on the causes of asthma and its treatment. After establishing the key role that mast cells play in the inflammatory response in asthma, attention was turned towards understanding disease chronicity and variability across the lifecourse. Through a combination of studies on airway biopsies and primary cell cultures we have established that asthma is primarily an epithelial disease driven by increased environmental susceptibility to injury and an altered repair response as depicted by sustained activation of the epithelial mesenchymal trophic unit (EMTU) that is invoked in foetal branching morphogenesis. Varied activation of the EMTU connects the origins of asthma to its progression over time with involvement of epithelial susceptibility through impaired barrier and innate immune functions and altered mesenchymal susceptibility as exemplified by polymorphisms of the metalloprotease gene, ADAM33. Taken together these observations have led to a fundamental re-evaluation of asthma pathogenesis. Rather than placing allergic inflammation as the prime abnormality, it is proposed that the airway epithelium lies at the center of asthma pathogenesis, and that in conjunction with the underlying mesenchyme, it is the principle orchestrator of both the induction of asthma and its evolution over the lifecourse. This concept has provided the basis for a new preventative and therapeutic approach focused more on increasing the airways’ resistance to environmental insults rather than suppressing downstream inflammation once it is established.

Key Words: Asthma; management; prevention; treatment

INTRODUCTION

Asthma is a chronic relapsing disease in which the airways in the lungs become constricted. The condition may be life-long, and the degree of obstruction changes over time. It is the commonest chronic lung disease and the UK has the highest prevalence worldwide: it affects 1 in 5 children and 1 in 12 adults. When I entered research in 1973, asthma was regarded as a disorder of “bronchospasm” treated symptomatically with unrestricted use of inhaled “bronchodilators”1 that is invoked in foetal branching morphogenesis. Varied activation of the EMTU connects the origins of asthma to its progression over time with involvement of epithelial susceptibility through impaired barrier and innate immune functions and altered mesenchymal susceptibility as exemplified by polymorphisms of the metalloprotease gene, ADAM33. Taken together these observations have led to a fundamental re-evaluation of asthma pathogenesis. Rather than placing allergic inflammation as the prime abnormality, it is proposed that the airway epithelium lies at the center of asthma pathogenesis, and that in conjunction with the underlying mesenchyme, it is the principle orchestrator of both the induction of asthma and its evolution over the lifecourse. This concept has provided the basis for a new preventative and therapeutic approach focused more on increasing the airways’ resistance to environmental insults rather than suppressing downstream inflammation once it is established.

INTRODUCTION

Asthma is a chronic relapsing disease in which the airways in the lungs become constricted. The condition may be life-long, and the degree of obstruction changes over time. It is the commonest chronic lung disease and the UK has the highest prevalence worldwide: it affects 1 in 5 children and 1 in 12 adults. When I entered research in 1973, asthma was regarded as a disorder of “bronchospasm” treated symptomatically with unrestricted use of inhaled “bronchodilators”. Since such treatment was linked to a dramatic increase in mortality linked to loss of bronchodilator responsiveness,1 there was an urgent need to understand more about its underlying mechanisms to provide a sound basis for its prevention and control.

Asthma is triggered by mast cells

Most asthma is associated with sensitisation of the airways to common allergens such as those from house dust mites. First we showed that, upon exposure to allergen, rapid airway narrowing (early response) was the result of IgE-dependent activation of airway mast cells with release of the rapidly acting granule-associated preformed mediators histamine and tryptase along with the newly generated products prostaglandin D₃, cysteinyl leukotrienes (LTC₄ and LTD₄),2 and adenosine³ acting together to contract airway smooth muscle, promote vascular leakage and stimulate mucus secretion. Airway mast cells were also shown to be a key source of small proteins (cytokines and chemokines) associated with the allergic response such as interleukins (IL)-4, IL-5, IL-6, and TNFα⁴ which, in concert with the inflammatory mediators, stimulate the recruitment and activation of secondary effector cells, starting with neutrophils, followed by eosinophils and then T lymphocytes to cause late phase airway narrowing and airway hyperresponsiveness.⁵ Mast cell mediator release was also shown to be responsible for acute airway narrowing in response to other stimuli such as exercise,
Mechanisms of asthma chronicity and severity

While allergen and other forms of bronchoprovocation gave us insight into selected inflammatory events, there was a need to uncover the mechanisms of asthma persistence. To do this we used fibreoptic bronchoscopy, tissue biopsy and lavage of the airways. Even in its mildest form, asthma displayed all the features of a chronic inflammatory disorder involving persistent mast cell, eosinophil and T-lymphocyte activation facilitated through the phased expression of adhesion molecules on microvessels by ongoing inflammatory mediator and cytokine release. The beneficial anti-inflammatory effect of corticosteroids was shown to be through depletion of mast cells, eosinophils and T-cells by depriving them of cytokines and chemokines required for their recruitment, activation and survival. As we investigated more severe disease, aspirin intolerance became an increasingly prominent. This subtype was caused by generation of high levels of LTC₄, from enhanced activity of the terminal enzyme in leukotriene synthesis LTC₄, synthase both in airway mast cells and eosinophils and helped explain the selective efficacy of leukotriene modifiers in this form of the disease. Other forms of severe asthma were characterised by high levels of IgE production. We showed that a chimeric IgG monoclonal antibody (mAb) directed to that part of the IgE molecule which bound with high affinity to the mast cell receptor (FcεRI) could effectively clear IgE by forming small immune complexes without triggering the allergic response. This laid the ground for the development of a humanised anti-IgE mAb, omalizumab, now used worldwide as the first biologic for the treatment of severe asthma. However, with a significant proportion of asthmatic patients experiencing incomplete or no benefit from allergen reduction strategies or anti-inflammatory treatment, it was becoming increasingly apparent that the disease was more than allergic airway inflammation.

Asthma as an epithelial disease

In 1989 we were the first to draw attention to the remodelling of the subepithelial basement membrane (BM) unique to asthma, and to suggest that this was the consequence of sustained epithelial injury, loss of cell attachment and activation of subepithelial myofibroblasts to secrete repair-type collagens. Using selective markers of epithelial injury and failing to repair adequately (summarized in ref. 11). Additional evidence for this has been our demonstration that the integrity of tight junctions, which control epithelial permeability and confer epithelial columnar cell stability and survival, is severely compromised in asthma. This barrier defect persists after passage in tissue culture indicative of an inherent defect independent of airway inflammation. Such a defect in physical barrier facilitates breaching of the epithelium by proinflammatory environmental insults such as allergens, microorganisms and pollutants to enhance local immune activation and inflammation. Thus, in contrast to a normal epithelium that heals by “primary intention” with no scar formation, that of asthmas is not only more susceptible to oxidant injury, but also responds in healing by “secondary intention” with excess secretion of growth factors to drive mucous metaplasia, fibrosis, angiogenesis and increased smooth muscle that characteristic of remodelling. To capture this concept, we propose that there is persistent activation of the EMTU involved in fetal branching morphogenesis. Novel approach to asthma connects the early life origins of the disease with the emergence of different endotypes, responses to treatment and natural history.

A key question that these studies raised is whether the epithelial “set point” for to environmental injury and repair in asthma is altered by activation of fundamental transcription factors such as SAM pointed domain-containing Ets transcription factor (spdef) and thyroid transcription factor 1 (TTF-1) involved in the regulation of goblet cell metaplasia and lung morphogenesis. In collaboration with Jeffrey Whittset at the Children’s Hospital in Cincinnati, we showed that TTF-1 was persistently suppressed in airway asthmatic epithelial cells which, in conditional TTF-1 deficient mice, translated into goblet cell induction and enhanced mucus secretion. In contrast, mucous metaplasia induced by aeroallergen was inhibited by epithelial overexpression of TTF-1. Application of transcriptomics to the airways of antigen sensitised and challenged TTF-1 over-expressing mice not only showed inhibition of genes controlling mucous production (e.g., spdef, calcium-activated chloride channel regulator 1 and 3, mucin-SAC), but also those involved in airway remodelling (e.g., trefoil factor, metalloprotease 12) and T cell-regulated allergic-type inflammation (e.g., IL-4, IL-13, chemokine (C-C motif) ligand 17). Ingenuity pathway analysis of the differentially expressed genes revealed that TTF-1 was an integral part of a gene network that controls mucous cell metaplasia, airway remodelling and allergic-type inflammation and has provided further support for the critical role played by the airway epithelium in orchestrating the multiple cellular events of asthma.

Remodelling of the airways characteristic of chronic asthma has been largely considered to be secondary to inflammation and yet anti-inflammatory drugs have only a partial beneficial effect. A further possibility is that distortion of a chronically damaged epithelium by repeated bronchoconstriction could drive remodelling as initially, a protective response. When early bronchoconstriction was provoked by inhaled allergen or methacholine in asthma, both produced similar increases in biomark-
Mechanisms and treatment of asthma exacerbations

An important component of asthma, accounting for most of the disease morbidity and mortality, is the exacerbation in which deterioration in disease control occurs over several days. After establishing PCR-based detection methods for human rhinoviruses (RV), we used longitudinal cohorts to first establish the importance of respiratory viruses in causing asthma exacerbations both in children (>85%)\(^1\) and in adults (>65%)\(^2\) with RV major and minor subtypes dominating. Controlled nasal infection of asthmatics with RV16 revealed a mixed eosinophilic and lymphocyte (CD4\(^+\) and CD8\(^+\)) airways inflammation of the lower airways in association with increased bronchial hyperresponsiveness which returned to baseline during convalescence.\(^3\) It was then important to understand why asthmatic airways were so susceptible to, what are usually regarded, as innocuous common cold viruses. After first showing that RV preferential infected the airway epithelium in asthma, we used primary epithelial cell monolayer cultures infected with major subtype RV16 subtype to pursue mechanisms. While bronchial epithelial cells (BECs) from normal subjects could effectively inhibit viral replication and eliminate remaining virus through activation of programmed cell death (apoptosis), BECs derived from asthmatic airways not only enabled the virus to survive but also to replicate eventually resulting in cytotoxic cell death, inflammatory mediator release and new virus shedding. This asthma-related epithelial defect was the result of impaired induction of interferon (IFN)-\(\beta\).\(^4\) In monolayer BEC cultures, the asthmatic defect in clearing virus could be corrected by applying a very

**Figure.** Schematic representation of the epithelial mesenchymal unit in chronic asthma. The epithelial set point for displaying an injury/repair phenotype is altered as a consequence of dysregulated expression of selected morphogenic transcription factors including sdef, FoxA2, TTF-1 and STAT 6. Increased expression of TTF1 and reduced expression of FoxA2 drives increased expression of spef and STAT6 linked to a propensity to undergo mucus metaplasia and drive a Th2 immune response. These and related epithelial signals also drive growth factor release to remodel the airways that in turn is linked to a defect in innate immunity e.g. IFN\(\beta\).
low dose of exogenous IFNβ and was interferon regulatory factor (IRF)-3-dependant. Thus the asthma “lesion” appeared to be in impaired signaling of viral RNA via microsomal toll-like receptor 3 to the initial induction of endogenous primary IFNs (step 1), leaving step 2 (the IRF-7-dependant induction of the anti-viral response via autacoid activation of the common IFNα/β receptor) intact. In a separate study transcriptomic and pathway analyses of circulating mononuclear cells before, during and after asthma exacerbations there occurs a distinct and systemic innate Type1 IFN response, but weaker B-cell antigen receptor and IL-4 adaptive immune response as compensation for the defect in mucosal innate immunity.20

In translating this to the clinic, a small amount of inhaled IFNβ would create a novel therapeutic approach to manage severe asthma exacerbations by restoring antiviral innate immunity to the epithelium. After first showing that inhaled rhIFN-β1a activates the airway antiviral pathways in asthma, we have now completed a successful Phase 2 clinical trial showing that inhaled rhIFN-β1a given at the start of a common cold was highly efficacious at blocking virus-related exacerbations in severe asthma in parallel to reducing viral load without any treatment-related side effects.

A new paradigm for asthma pathogenesis

Taken together, this research has created a new paradigm for asthma that places the airway epithelium at the center of disease pathogenesis (Figure).21 In orchestrating how the airways respond to a variety of environmental exposures, the epithelium and underlying mesenchyme are well positioned to control not only the inflammatory response, but also structural changes in the airways associated with different asthma phenotypes, treatment responses and disease evolution over the lifecourse. These discoveries provide a strong basis for creating novel therapies that are more directed towards increasing the lung’s resistance to the inhaled environment rather than concentrating all efforts on trying to suppress inflammation once it is established.
