Background: Human retinal pigment epithelial cells are promising target sites for small interfering RNA (siRNA) that might be used for the prevention and/or treatment of choroidal neovascularization by inhibiting the expression of angiogenic factor; for example, by downregulating expression of the vascular endothelial growth factor gene.

Methods: A novel functional lipid, DSPE-PEG-RGD, a Arg(R)-Gly(G)-Asp(D) motif peptide conjugated to 1, 2-distearoyl-sn-glycero-3-phosphoethanolamine- N-[maleimide (polyethylene glycol)-2000], was synthesized for the preparation of siRNA-loaded RGD-PEGylated liposomes to enhance uptake of encapsulated siRNA in retinal pigment epithelial cells. Various liposomes, with 1 mol% and 5 mol% PEGylated lipid or 1 mol% and 5 mol% RGD-PEGylated lipid, were fabricated.

Results: Characterization of the liposomes, including siRNA entrapment efficiency, average particle size and ζ-potential, were determined to be as follows: >96%, 129.7 ± 51 to 230.7 ± 60.7 nm, and 17.3 ± 0.6 to 32 ± 1.3 mV, respectively. For the in vitro retinal pigment epithelial cell studies, the RGD-PEGylated liposomes had high delivery efficiency with siRNA delivery, about a four-fold increase compared with the PEGylated liposomes. Comparison of the various liposomes showed that the 1 mol% RGD-modified liposome had less cytotoxicity and higher siRNA delivery efficiency than the other liposomes. The antibody blocking assay confirmed that uptake of the 1 mol% RGD-PEGylated liposome was via integrin receptor-mediated endocytosis in retinal pigment epithelial cells.

Conclusion: The results of this study suggest that RGD-PEGylated liposomes might be useful for siRNA delivery into retinal pigment epithelial cells by integrin receptor-mediated endocytosis.

Keywords: Arg-Gly-Asp, RGD, small interfering RNA, liposome, retinal pigment epithelial cells

Introduction
Gene therapy is thought to have great potential for treatment of acquired diseases, as well as inherited genetic diseases.1 Many human diseases, eg, cancer and neovascularization, have been associated with overexpression of specific genes. The delivery of a normally functioning gene to the nucleus or cytoplasm of malfunctioning cells, may restore the targeted abnormal gene to a normal state.2,3 Human retinal pigment epithelial cells play an important role in angiogenesis of the choroid by overexpression of angiogenic factors. Small interfering RNA (siRNA) is a double-stranded structure with 21–23 base pairs that can target its complementary mRNA, thereby hastening mRNA degradation, and inhibiting translation of a targeted gene.4,6 With high specificity and easy application, siRNA has gradually replaced more conventional gene...
knockdown techniques for target-specific gene silencing. The ability of siRNA to silence gene expression has become a useful tool for investigating gene function; in addition, it is used in the pharmaceutical industry to develop pharmacological agents.7 Thus, retinal pigment epithelial cells might be a promising target site for siRNA to prevent or treat choroidal neovascularization in patients with age-related macular degeneration by inhibiting expression of angiogenic factor. However, use of siRNA as a therapeutic agent has been complicated by problems such as poor formulation stability, difficulty penetrating biological barriers, and low delivery efficiency at the target site. Therefore, it is important to develop a delivery system that serves as an effective vector for siRNA and provides optimal delivery to the targeted site.5,8

Cationic liposomes are a promising nonviral delivery system, and have been extensively studied for siRNA and plasmid DNA delivery.9 The addition of polyethylene glycol (PEG) to the liposomes can decrease reticuloendothelial system recognition, thereby prolonging the circulation time in biological fluids. Although PEGylated liposomes provide a more stable preparation, the steric barrier of the grafted PEG moiety on the surface of the liposomes reduces interaction between the delivery system and the cell surface. Many strategies have been successfully implemented to improve cell delivery efficiency of the PEGylated nanoparticles including transient PEG coating, attachment of targeting ligands at the distal end of PEG moieties, and the incorporation of cell-penetrating peptides.10,11 Currently, liposome studies are focusing on targeting delivery to maximize the delivery of the carried therapeutic agent to the targeting site and minimizing potential side effects. The addition of specific antibodies or a biological adhesive cell ligand to the liposome can enhance its binding ability in specific tissues, cells or pathogens, and consequently achieve higher delivery efficiency. For enhancing siRNA delivery into retinal pigment epithelial cells, the ligand of the surface receptors in the retinal pigment epithelial cells might be used to modify the PEGylated lipid of the liposome. Previous studies have shown that integrin receptors are upregulated in ocular neovascularization. Specifically, integrin αVβ3 is overexpressed in the ocular tissues of patients with age-related macular degeneration, whereas, αVβ3 and α5β1 are also found in the vascular tissues of patients with proliferative diabetic retinopathy.12 Other studies showed that, in retinal pigment epithelial cells, the αVβ3 and α5β1 receptors were expressed at the apical side, while integrin α5β1 receptors were expressed at the basolateral side.13 Expression of α5β1 integrins on the basolateral side of retinal pigment epithelial cells has been characterized and shown to be important for attachment of cells to Bruch’s membrane. Expression of αVβ3 and α5β1 integrins at the apical side has been associated with maintenance of diurnal phagocytosis of the shed photoreceptor outer segment fragment.14 In order to enhance the delivery of siRNA-loaded liposomes to retinal pigment epithelial cells, liposomes with the integrin receptor ligand might be used to target delivery of siRNA to retinal pigment epithelial cells for the prevention and/or treatment of choroidal neovascularization in patients with age-related macular degeneration. Moreover, peptides with the RGD motif have been shown to bind specifically to α5- or αV-associated integrins.15,16 Thus, modified liposomes with the RGD motif peptide might be constructed to carry siRNA for targeted delivery.

The purpose of this study was to synthesize a functional RGD peptide-lipid conjugate and develop an effective lipid-based gene vector associated with the RGD peptide for targeting integrin receptors and enhancing siRNA delivery to retinal pigment epithelial cells. In addition, the characterization, cytotoxicity, and delivery efficiency of the liposome preparations were investigated.

Materials and methods

Chemicals

A negative control siRNA or FAM-labeled negative control siRNA (having a molecular mass of approximately 13.5 kDa, sense: FAM-5′-UUC-UCC-GAA-CGU-GUC-ACG-U TT-3′ and antisense: 5′-ACG-UGA-CAC-GUU-CGG-Aga-ATT-3′) were purchased from MDBio Inc (Taipei, Taiwan). All of the lipid materials used, 3β-[N-(N′-dimethylaminoethane)-carbamoyl] cholesterol (DC-cholesterol), 1,2-dioleoyl-sn-glycero-3-phosphoethanolamine (DOPE), 1,2-distearoyl-sn-glycero-3-phosphoethanolamine-N-[carboxy(polyethylene glycol)-2000] [DSPE-PEG(2000) carboxy], and 1,2-distearoyl-sn-glycero-3-phosphoethanolamine-N-[maleimide (polyethylene glycol)-2000] [DSPE-PEG(2000) maleimide] were obtained from Avanti Polar Lipids (Alabaster, AL). The RGD peptide (sequence: H-Gly-Arg-Gly-Asp-Pro-Lys-Cys-OH, molecular weight, 818.9 Da) was purchased from Yao-Hong Biotechnology Inc (Taipei, Taiwan). CHCA (α-cyano-4-hydroxycinnamic acid) was obtained from Sigma-Aldrich (St Louis, MO). The SYBR Gold, Hoechst 33342, and BODIPY phallolidin dyes were obtained from Invitrogen (Eugene, OR). The MTS reagent, 3-[4,5-dimethylthiazol-2-yl]-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium, was purchased from Promega Corporation (Madison, WI). Anti-integrin antibodies (αVβ3, MAB1976; α5β1, MAB1969; αs, CBL497) were obtained from...
Chemicon International (Temecula, CA). All other chemicals were pharmaceutical or reagent grade.

**Synthesis and identification of DSPE-PEG(2000)-RGD**

RGD peptide-conjugated DSPE-PEG(2000) maleimide [DSPE-PEG (2000)-RGD] was synthesized by modifying a method previously reported. Briefly, DSPE-PEG(2000) maleimide ammonium salt (molecular weight 2941.61) and RGD peptide were dissolved in a buffer solution (50 mM triethanolamine hydrochloride, 50 mM sodium phosphate, 150 mM NaCl, and 1 mM EDTA, pH 8). DSPE-PEG(2000) maleimide solution (2 mM) was gently mixed with an equal volume of RGD peptide solution (4 mM) overnight in a glass bottle at 4°C. The synthesized product was identified by matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry (Bruker Daltonics, Autoflex II TOF/TOF50, Leipzig, Germany).

**Preparation of siRNA-loaded liposomes**

PEGylated cationic liposomes, containing DC-cholesterol, DOPE, and DSPE-PEG(2000) carboxy with molar ratios of 50/49/1 and 50/45/5, were prepared by the thin-film hydration method according to a method previously reported. Briefly, the lipids were dissolved in chloroform in a rotary bottle (total lipids 3.6 µmol). After evaporation, a thin lipid film was formed and further dried under a vacuum for eight hours to remove residual solvent. The dry lipid film was hydrated for eight hours using 2.4 mL sterile phosphate-buffered solution containing siRNA or FAM-labeled siRNA. The dispersion was sonicated for 10 minutes and then passed through a polycarbonate membrane 10 times (100 nm pore size) using an extruder (Avanti Polar Lipids, Mini-Extruder, Birmingham, AL). The total lipid concentration of the prepared liposomes was 1.5 mM.

**Preparation of siRNA-loaded liposomes with RGD peptide modification**

RGD-modified PEGylated cationic liposomes, containing DC-cholesterol, DOPE, and DSPE-PEG(2000)-RGD, with molar ratios of 50/49/1 and 50/45/5, respectively, were prepared. The procedure was the same as described above.

**Characterization of siRNA-loaded liposomes**

**Particle size**

The prepared siRNA-loaded liposomes (1.5 mM) were diluted to 1 mM using an appropriate volume of sterile phosphate-buffered solution (pH 7.3). The volume-average hydrodynamic diameter of various siRNA-loaded liposomes was determined by a dynamic light scattering method using a particle analyzer (Horiba Instruments Limited, LB-500, Tokyo, Japan). A laser diode was used for dynamic light scattering, with a LB-550 software system from Horiba Instruments Limited. The apparatus consisted of a digital correlator and a signal processor incorporated in a computer. Measurements were made at 650 nm, at a 90° angle for the detector (photo multiplier tube). The mean particle size and size distribution of the siRNA-loaded liposomes were obtained for each sample measurement at room temperature.

**Zeta potential**

The prepared siRNA-loaded liposomes (1.5 mM) were diluted to 1 mM using an appropriate volume of sterile phosphate-buffered solution (pH 7.3). The zeta potential of the siRNA-loaded liposomes was measured by determining the electrophoretic mobility using the zeta potential analyzer (Brookhaven Instruments, ZetaPlus, Long Island, NY) at room temperature. Triplicate measurements were performed for each sample.

**Transmission electron microscopy**

For the transmission electron microscopy, the siRNA-loaded liposome solution (8 µL) was placed on a formvar/carbon film-coated copper grid, obtained from Ted Pella (Redding, CA). After removing excess sample with filter paper, the sample was air-dried for 10 minutes at room temperature. The siRNA-loaded liposomes were then visualized using 0.5% uranyl acetate negative staining for 15 seconds at room temperature and imaged on a transmission electron microscope (Hitachi, H-7650, Tokyo, Japan). Images were taken at 50,000× magnification.

**Entrapment efficiency**

For determination of the entrapment efficiency of the PEGylated liposomes and RGD peptide-modified PEGylated liposomes, the amount of negative control siRNA was quantified in the external phase, according to methods previously reported. The liposomes were spun down at 20,000 x g for 30 minutes; the supernatants were diluted (if necessary), and stained with SYBR Gold dye and analyzed for siRNA content by measuring the intensity of fluorescence with an enzyme-linked immunosorbent assay reader (Biochrom Ltd, Anthos 2010, Cambridge, UK) at 537 nm against a standard curve. A standard curve was established from analyzing a series of siRNA reference solutions with 200 µL measured by an enzyme-linked immunosorbent assay reader, and determined
fluorescence intensity of 537 nm. The regression equations were as follows: 
\[ y = 11.343x - 221.91, \text{r square} = 0.9992. \]
The regression lines had good linearity, ranging from 31.25 to 2000 ng/mL for siRNA. The entrapment efficiency of the siRNA-loaded liposomes was calculated as the ratio of siRNA used for preparation of the initial mixture as follows: 
\[ \text{Entrapment efficiency} \% = \frac{\text{siRNA}_t - \text{siRNA}_f}{\text{siRNA}} \times 100; \]
where siRNA, is the total amount of siRNA used for preparation of the initial mixture and siRNAf is the free siRNA amount recovered in the supernatant. All the measurements were done in triplicate.

ARPE-19 cell cultures
ARPE-19 cells were obtained from the American Tissue Culture Collection and cultured in a 1:1 mixture of Dulbecco’s modified Eagle’s medium (DMEM) and Ham’s F12 with 15 mM HEPES buffer, 2 mM L-glutamine, 56 mM sodium bicarbonate, and 10% fetal bovine serum. The cells were maintained at 37°C in a humidified atmosphere with 5% CO₂. Cells in passages 25 to 32 were used in the experiments, and seeding cells were counted in a hemocytometer with Trypan blue staining.

Liposomal cytotoxicity
ARPE-19 cells were seeded in 96-well plates at a density of 1.6 × 10⁴ cells per well and incubated for 18 hours. Before the MTS assay, cells were washed with phosphate-buffered solution 100 µL. A 1.5 mM total lipid concentration of the prepared liposomes was diluted to 51.2, 12.8, and 3.2 µM with serum-free culture medium. The siRNA-loaded liposomes were then added to 100 µL of serum-free culture medium. After four hours, the cells were washed with phosphate-buffered solution 100 µL, and 100 µL of the cultured media was then added. Next, the cells were added to 20 µL of MTS and incubated for two hours at 37°C. An enzyme-linked immunosorbent assay reader, set at 490 nm, was used to read the absorbance of formazan in each well to determine the quantity of mitochondrial dehydrogenases in the viable cells. The percent cell viability was calculated as: 
\[ \text{cell viability} \% = \frac{\text{ABS}_{\text{sample}} - \text{ABS}_{\text{blank}}}{\text{ABS}_{\text{control}} - \text{ABS}_{\text{blank}}} \times 100, \]
where ABSsample, ABScontrol, and ABSblank represent the absorbance of wells exposed to the liposomal dispersions, treated with serum-free culture medium, and treated with serum-free culture medium but without cells, respectively.

Confocal laser scanning microscopy
The ARPE-19 cells were seeded in six-well plates using DMEM medium at a density of 2 × 10⁴ cells per well and incubated for 24 hours to achieve 50% confluence. Before the uptake study, the culture media was removed, and the cells were washed with phosphate-buffered solution. The phosphate-buffered solution was then removed, and the prepared FAM-siRNA loaded liposomes, in 1 mL of serum-free culture media, were added. After four hours, the cells were washed three times with phosphate-buffered solution. The cells were then fixed with 3.7% formaldehyde for 10 minutes and washed three times with 1 mL of phosphate-buffered solution. Finally, cellular permeability was increased by adding 0.1% Triton for five minutes, and washing three times with 1 mL of phosphate-buffered solution. The cells were incubated in Hoechst 33342 for five minutes, which was then replaced by BODIPY phalloidin for 20 minutes. Confocal laser scanning microscopy (Jeol Ltd, Leica TCS SP5, Tokyo, Japan) was performed to obtain optical images of the distribution of FAM-siRNA in the ARPE-19 cells. Images obtained from the bottom of the coverslip to the top of the cells were recorded by confocal laser scanning microscopy (CLSM). The number of speckled green fluorescence images of the FAM-siRNA located within the cytoplasm was counted from the Z-series images at every 1 µm of depth. For determination of the FAM-siRNA localized within the cell, the number of speckled green fluorescence images counted was divided by total cell number observed in each image. The figure was determined by the distance of the Z-axis from the bottom of the coverslip versus the number of speckled green fluorescence (FAM-siRNA) images counted in the cytoplasm of each cell.

Flow cytometry
The ARPE-19 cells were seeded in six-well plates using DMEM medium at a density of 3 × 10⁴ cells per well and incubated for 24 hours to achieve 75% confluence. Before the uptake study, the culture media was removed and the cells were washed with phosphate-buffered solution. FAM-siRNA loaded liposomes in 1 mL of serum-free culture media were then added. After four hours, the cells were washed three times with phosphate-buffered solution and then detached using 0.05% trypsin/0.02% EDTA, washed with phosphate-buffered solution, and resuspended in 1 mL phosphate-buffered solution for flow cytometric assay. The FAM-siRNA loaded liposome uptake was measured using a flow cytometer (Becton Dickinson, FACScan flow cytometer, Heidelberg, Germany). The ARPE-19 cells were then analyzed at 488 nm excitation and 530 nm band-pass filter in the emission path. Forward and side light scatter was used to gate the desired scattered events of the normal cells, dead cells, and cell debris.
Antibody blocking assay of FAM-siRNA loaded liposomes

Previous studies have shown that ARPE-19 overexpresses various integrins and serves as an in vitro cell model for gene delivery.\textsuperscript{23,24} In order to confirm that receptor-bearing cells take up the RGD-modified PEGylated liposome, ARPE-19 was incubated with FAM-siRNA-loaded 1 mol% RGD-PEGylated liposomes at 37°C. To determine that specific receptors were used in the uptake of 1 mol% RGD-PEGylated liposomes by ARPE-19, the cells were pretreated with antibodies that block α\textsubscript{v}β\textsubscript{3} (MAB1976), α\textsubscript{v}β\textsubscript{1} (MAB1969), and α\textsubscript{v} (CBL497) integrins. All antibodies were used at 5 μg/mL.\textsuperscript{25} The ARPE-19 cells were seeded in six-well plates using DMEM medium at a density of 3 × 10\textsuperscript{5} cells per well and incubated for 24 hours to achieve 75% confluence. Before treating the FAM-siRNA loaded liposomes, the cells were preincubated separately with α\textsubscript{v}β\textsubscript{3} antibody, α\textsubscript{v} antibody, or α\textsubscript{v}β\textsubscript{1} antibody, for one hour and then FAM-siRNA loaded liposomes were added. After two hours, the cells were washed three times with phosphate-buffered solution and then detached using 0.05% trypsin/0.02% EDTA, washed with phosphate-buffered solution, and resuspended in 1 mL of phosphate-buffered solution for the flow cytometry assay.

Statistical analysis

The results are expressed as the mean ± standard deviation. The Student’s t-test for the comparisons between two means was used to determine statistical significance. Differences were considered to be significant at \( P < 0.05 \).

Results

Synthesis and identification of DSPE-PEG-RGD

Under the reaction conditions of 12 hours at 4°C, pH 8, and gentle mixing, DSPE-PEG(2000)-RGD (molecular weight 3741.69 Da) was successfully synthesized using DSPE-PEG(2000) maleimide (molecular weight 2922.79 Da) and thiolated RGD peptide (molecular weight 818.9 Da), by a Michael additive reaction between activated maleimide and a thiol group (Figure 1A). Formation of the desired compound was further confirmed by the MALDI-TOF mass. Peaks of parental DSPE-PEG(2000) maleimide completely vanished and shifted to the right side, at regions approximating the molecular weight of the thiolated RGD peptide (Figure 1B). DSPE-PEG maleimide was not a homogenous polymer compound. The successive members in DSPE-PEG(2000)-RGD or DSPE-PEG(2000) maleimide differed in mass by 44 Da for the ethylene oxide —CH\textsubscript{2}CH\textsubscript{2}O— molecular weight.

Characterization of siRNA-loaded liposomes

The characterization of the liposomes, including particle sizes, zeta potential, and entrapment efficiency, is summarized in Table 1. The mean particle sizes for the 1 mol% and 5 mol% PEGylated liposomes with siRNA were 129.7 nm and 147.2 nm, respectively. Mean particle size increased slightly by increasing the molar ratio of the PEGylated lipids.

In addition, the RGD-PEGylated liposomes with siRNA had larger mean particle sizes than the PEGylated liposomes. The transmission electron microscopic images of the 1 mol% PEGylated liposomes and 1 mol% RGD-PEGylated liposomes showed a similar particle size distribution as measured by the dynamic light scattering method (Figure 2A and B). The siRNA-loaded 1 mol% PEGylated liposome had the highest positive zeta potential (32 ± 1.34 mV) of all the liposomes studied. When a high molar ratio of DSPE-PEG(2000) carboxy was incorporated, the zeta potential was reduced to 25.7 ± 1 mV for the 5 mol% PEGylated liposomes. In addition, incorporation with different molar ratios of the synthesized lipid, DSPE-PEG(2000)-RGD, reduced the zeta potential to 24.9 ± 1.5 for the 1 mol% RGD-PEGylated and to 17.3 ± 0.6 mV for the 5 mol% RGD-PEGylated liposomes. The PEGylated liposomes and RGD-PEGylated liposomes showed high-level siRNA entrapment efficiencies of more than 96% by the thin film hydration method.

Liposome cytotoxicity

The cytotoxicity of the liposome formulations was evaluated in the ARPE-19 cells with total liposomal lipid concentrations of 3.2, 12.8, or 51.2 μM for the cells incubated with serum-free medium alone, no treatment with liposome as a control, and cell viability set at 100% (Figure 3). The viability of ARPE-19, the group treated with 12.8 μM of 1 or 5 mol% RGD-PEGylated liposomal suspensions, showed a relative cell viability that remained unchanged. However, there was significantly reduced relative cell viability when the cells were treated with 12.8 μM of 1 mol% and 5 mol% PEGylated liposomes. There was no cytotoxicity among the groups treated with 3.2 μM, but significant cytotoxicity was observed with the 51.2 μM treatment. These results show that RGD peptide modification of cationic PEGylated liposomes was less cytotoxic than the cationic PEGylated liposomes.

CLSM imaging study

The distribution of FAM-siRNA-loaded liposomes was studied to determine their intracellular distribution with or without DSPE-PEG-RGD. Figure 4 shows the confocal
images of FAM-siRNA-loaded RGD-PEGylated liposomes; they had a significantly greater amount of speckled green fluorescence (FAM-siRNA) in the ARPE-19 cells compared with the cationic PEGylated liposomes (4B > 4A, 4D > 4C). Slightly more FAM-siRNA was detected in the 1 mol% PEGylated liposomes compared with 5 mol% PEGylated liposomes (4A > 4C). These findings suggest that high levels of PEGylation in the liposomes decreased uptake of FAM-siRNA in the loaded liposomes. However, FAM-siRNA was significantly greater
in the 1 mol% RGD-PEGylated liposomes compared with the 5 mol% RGD-PEGylated liposomes (4B > 4D). A three-dimensional detection method was used by the CLSM for determination of FAM-siRNA loaded liposomes localized within the cell. Comparison of 1 mol% PEGylated liposomes with 1 mol% RGD-PEGylated liposomes (Figure 5A and B) showed that the 1 mol% RGD-PEGylated liposomes were more localized than the 1 mol% PEGylated liposomes (5B > 5A). The total number of 1 mol% PEGylated liposomes and 1 mol% RGD-PEGylated liposomes was counted as 40 and 89, respectively. These findings suggest that the RGD-PEGylated liposomes may provide an efficient transfer of siRNA for delivery into ARPE-19 cells.

Liposome uptake by ARPE-19 cells
The FAM-siRNA uptake intensity in the ARPE-19 cells was studied to evaluate the PEGylated liposomes and RGD-PEGylated liposomes; flow cytometry was used for the analysis. Comparison in the presence and absence of RGD-PEGylated effects in the formulation of 1 mol% and 5 mol% RGD-PEGylated liposomes, showed FAM-siRNA delivery efficiencies of about 3.6 times and 4.2 times greater than for 1 mol% and 5 mol% PEGylated liposomes, respectively (Figure 6B and C). For the 1 mol% and 5 mol% PEGylated liposomes, the FAM-siRNA delivery efficiency decreased as the percentage of PEGylated lipids increased in the formulation. In the 1 mol% and 5 mol% RGD-PEGylated liposomes, the FAM-siRNA delivery efficiency was also decreased as the percentage of DSPE-PEG-RGD increased in the formulation. Similar trends were observed in the results of the CLSM imaging study. These findings might be explained by the RGD peptide modification of the PEGylated liposomes enhancing the delivery efficiency of the cargo gene, FAM-siRNA, into the ARPE-19 cells. From the image of the forward and side light scatter, cell debris was significantly observed in the 5 mol% PEGylated liposomes, but was not obvious in the 5 mol% RGD-PEGylated liposomes. These findings suggest that PEGylated lipid interferes with the integrity of the cell and that DSPE-PEG-RGD is less prone to induce cell damage.

Antibody blocking assay
Comparison of the uptake of FAM-siRNA loaded 1 mol% PEGylated liposomes of cells with or without antibody pretreatment; the group without antibody pretreatment was used as a control, and the FAM-siRNA uptake intensity was set at 100%. The pretreatment of anti-α, β, or α, β antibody uptake percentage was decreased to 23.2% (P < 0.01), 31.9% (P < 0.001), and 34.1% (P < 0.001), respectively (Figure 7). When pretreated with a mixture
have also been studied. However, previous studies have usually prepared the nanoparticles first, and then added a targeting molecule for conjugation on the surface of the nanoparticle. This method is limited by the difficulty in controlling the number of targeting moieties conjugated to the constructed nanoparticles. In this report, synthesis of the ligand-conjugated lipid, DSPE-PEG-RGD, was performed by Michael addition reactions between activated maleimide and thiol groups prior to preparation of the liposomes (Figure 1A). The DSPE-PEG-RGD was easy to synthesize, allowing precise addition of the targeting molecule in a variety of liposome preparations. In this study, MALDI-TOF mass spectrometry, a powerful tool for identification of a compound’s molecular weight, was used to determine the molecular weight of DSPE-PEG maleimide and DSPE-PEG-RGD. MALDI-TOF mass spectrometry showed that the DSPE-PEG-RGD peaks all increased approximately 818.9 Da, which is the molecular weight of thiolated RGD peptide, compared with the relative DSPE-PEG maleimide peaks (Figure 1B). After reaction, the parental DSPE-PEG maleimide peaks were almost gone, and instead DSPE-PEG-RGD peaks were observed. These results showed that the DSPE-PEG maleimide reacted quantitatively with one thiolated RGD peptide.

**Discussion**

Because it is difficult for free siRNA to enter into cells, lipid-based carriers are often used to improve cellular uptake of siRNA. Previous studies have reported that cationic liposomes can be used for gene delivery; they are easy to prepare, reasonably inexpensive, and can achieve ideal transfection. Currently, the targeting liposome design is of great interest for the transport of genes into desired target cells; this method has the potential to produce greater and more selective therapeutic activity. This approach involves the coupling of targeting moieties capable of recognizing target cells, binding to them, and internalization of the liposomes and encapsulated gene. For this process, a variety of targeting liposomes can be developed. For example, an antibody-mediated liposome, or an immunoliposome, can be constructed to target HER2-overexpressing tumors using anti-HER2 liposomes. Other ligands such as folate, transferrin, RGD peptide, and the epidermal growth factor receptor of -α5β3, -α5β1, and -α5 antibodies, the uptake percentage was decreased to 49.5% \( (P < 0.001) \) compared with no pretreated antibody control. These data further confirmed that the RGD-PEGylated liposomes were internalized by integrin receptor-mediated endocytosis in ARPE-19 cells.
The PEG moiety of the liposome has been demonstrated to be more stable and remains in the circulation for a longer period of time in vivo, because the PEG moiety provides an efficient steric hindrance that prevents the binding of plasma proteins with the liposomes and thereby also interferes with uptake by the reticuloendothelial system.10,29,31 In this study, the zeta potential of the siRNA-loaded 1 mol% PEGylated liposome was highly positive (32 ± 1.3 mV). However, when a high molar ratio of DSPE-PEG was incorporated, it was reduced to 25.3 ± 1 mV for the 5 mol% PEGylated liposomes. Incorporating different molar ratios of DSPE-PEG-RGD resulted in further reductions in the zeta potential to 24.9 ± 1.5 mV for the 1 mol% RGD-PEGylated liposomes and to 17.3 ± 0.6 mV for the 5 mol% RGD-PEGylated liposomes (Table 1). These findings show that the presence of a lipid-bound PEG moiety shielded the positive charge from the cationic lipid, and the presence of a RGD peptide at the end of PEG moiety shielded the molecule from a more positive charge.

In 1 mol% PEGylated liposomes and 1 mol% RGD-PEGylated liposomes, the hydrodynamic size was in the range of 129.7 to 156.4 nm, associated with a narrow size distribution of 51 to 37.5 nm, respectively. The presence of the RGD peptide on the liposome surface slightly increased the size compared with liposomes without the RGD peptide. Theoretically, for a 100 nm liposomal particle modified with DSPE-PEG2000, the PEG moiety is arranged in the mushroom mode in the presence with <4 mol% DSPE-PEG2000; the PEG moiety is configured in phase transition by the presence of a 4 to 8 mol% modification, and in the brush mode with >8 mol% PEGylation.32 The effect of grafted PEG on liposome size is mainly a change in the spatial structure of the DSPE-PEG molecule, which is contingent on the grafted PEG in the mushroom or brush configuration.33

The transmission electron microscopic assay showed clearly the image of the small unilamellar vesicles that comprise the lipid bilayer, with diameters in the range of 50–250 nm; a narrow size distribution was observed (Figure 2). The small unilamellar vesicles contain a large aqueous core and are preferentially used for encapsulated water-soluble drugs.10 These findings indicate that the DSPE-PEG-RGD incorporated into the liposome resulted in sterically stabilized liposomes as well as PEGylated liposomes.

In this study, siRNA entrapment efficiencies were all higher than 96%. This was primarily due to the electrostatic interaction between the dimethylaminoethane of the DC-cholesterol and the phosphate groups of the siRNA in a +/− charge ratio of 4, consistent with previously reported findings from Zhang et al.34

Liposomes are composed of phospholipids and cholesterol, which are components of the cell; these compounds are biocompatible and nontoxic particulates that can be used for gene carrier constructs. However, there are some components reported that tend to be associated with cytotoxicity. For example, positively charged liposomes containing DC-cholesterol had increased toxicity when their dimethylaminoethane content was increased;35 the liposome formulations included a lipid holding a PEG moiety to reduce the surface charge density of the cationic lipid. However, as the PEG molecular weight of the PEGylated nanoparticle increased, the cytotoxicity also increased.36 In this study, the cytotoxicity caused by the RGD-PEGylated liposome was lower than for the PEGylated liposome; these findings suggest that RGD peptide modification reduced the toxicity of the PEG portion of the liposome structure. With the concentration of the RGD-PEGylated liposome in the culture medium less than 12.8 µM, the biosafety of the delivery system was improved in ARPE-19 cells (Figure 3). Hence, this safe concentration was used in the subsequent siRNA delivery assay.
The liposomal surface charge is considered one of the most important parameters governing cellular uptake of nanoparticles, which occurs by the electrostatic interactions of oppositely charged cells and liposomes.\textsuperscript{37,38} PEGylated liposomes decreased the uptake of the liposome and its cargo gene, FAM-siRNA (Figure 4A and C); this resulted from not only a lower positive charge on the liposome surface, but also the ability of the PEG moiety of the liposome to prevent contact with the cell surface. These properties minimize the nonspecific binding of liposomes to the cell surface.\textsuperscript{39,40} However, in order to accumulate more liposomal siRNA in the retinal pigment epithelial cells, with the goal of producing greater and more selective therapeutic activity, use of active targeted liposomes with the RGD peptide has been suggested. This involves coupling RGD moieties capable of recognizing and binding to the integrin receptor of the retinal pigment epithelial cells, and then inducing liposome or loaded siRNA uptake. The expression of $\alpha_5\beta_1$ integrins on the basolateral

**Figure 5** Three-dimensional confocal images showing the intracellular location of FAM-siRNA-loaded liposomes (green) in ARPE-19 cells, four hours after administration, at 100× magnification: 1 mol% PEGylated liposomes (top figure); 1 mol% RGD-PEGylated liposomes (bottom figure). The number of speckled green fluorescence images of FAM-siRNA located within the cytoplasm were counted at each Z-series image (right of figure). The cell nuclei were stained with Hoechst 33342 (blue), and the cell was stained with BODIPY phalloidin (red).

Figure 6 Various amounts of FAM-siRNA loaded liposome uptake as measured by flow cytometry. (A) Forward and side light scatter were used to gate the desired scattered events (normal cells) from dead cells and cell debris. (B) In the normal cells, uptake intensity of FAM-siRNA loaded liposome preparations (green histogram) was compared with the untreated control (block histogram). (C) Fluorescence intensity of FAM-siRNA-loaded liposome preparations in the normal cells expressed as an intensity ratio by dividing by the untreated control.

Notes: Data are expressed as the mean ± SD for N = 3. (Student’s t-test: *P < 0.01 or **P < 0.005, RGD peptide-modified liposomes compared with non-RGD peptide-modified liposomes; 5 mol% compared with 1 mol%).

Abbreviations: FAM, fluorescein-labeled; siRNA, small interfering RNA; SD, standard deviation.

side of retinal pigment epithelial cells has been characterized, and shown to be important for attachment of cells to Bruch’s membrane, while expression of the α₅β₁ and α₅β₁ integrins on the apical side maintains diurnal phagocytosis of the shed outer segment fragment of the photoreceptor. The RGD-containing peptide could be used as a specific ligand for integrin α₅β₁, α₅β₁, or α₅β₁. Therefore, the synthesized DPSE-PEG-RGD was used to formulate targeted liposomes in this study by covalent binding of the active maleimide of the PEG end and the specific thiol group of ligands.

For the siRNA, the interference mechanism is necessary for successful delivery of siRNA into the cytoplasm.
of target cells. In further analysis of the CLSM images, comparing the 1 mol% RGD-PEGylated liposomes with the 1 mol% PEGylated liposomes, the total number of 1 mol% RGD-PEGylated liposomes localized within the cells was more than for the 1 mol% PEGylated liposomes (Figure 5A and B). Therefore, a large amount of the FAM-siRNA-loaded 1 mol% RGD-PEGylated liposomes was confirmed to provide effective delivery into the cytoplasm of the ARPE-19 cells. However, siRNA delivery is a multistep process, which has several potential problems, including biological barriers to penetration, cellular internalization, endosomal escape, and cytoplasm trafficking.5,34

In the future, the knockdown effect of targeted liposomes encapsulating a functional siRNA and the therapeutic effects in vivo of targeted delivery will require further evaluation.

Previous reports have shown that a suitable size and positive zeta potential are essential for enhanced delivery of particles into cells.41 The results of this study show that RGD-PEGylated liposomes have a larger size and smaller zeta potential, but increased siRNA delivery efficiency in ARPE-19 cells, compared with PEGylated liposomes (Figure 6). Demonstrating further that binding was mediated by RGD-associated integrin receptors, the data from the integrin -α₅β₁, -α₅β₁, and -α₅ antibody blocking assay showed that RGD-modified PEGylated liposomes were internalized by integrin receptor-mediated endocytosis in the retinal pigment epithelial cells. However, the fluorescence of FAM-siRNA-loaded 1 mol% RGD-PEGylated liposomes was not completely inhibited by pretreating the cells with blocking antibodies against α₅β₁, α₅β₁, and α₅ integrins (Figure 7). The integrin family includes not only α₅β₁ and α₅β₁, but also α₅β₁, α₅β₁, α₅β₁, and α₅β₁, which recognize RGD-containing peptides.42

**Conclusion**

The results of this study showed successful synthesis of the functional lipid, DSPE-PEG-RGD, which could be incorporated into a liposome formulation that was prepared and loaded with siRNA for effective delivery into ARPE-19 cells. The prepared siRNA-loaded 1 mol% RGD-PEGylated liposomes demonstrated a positive charge (24.9 ± 1.5 mV), a nanosize of 156.4 nm (with narrow distribution width of 37.5 nm), entrapment efficiency (98.83% ± 0.01%),
low cytotoxicity, and a high level of siRNA delivery efficiency compared with other investigated liposome vehicles. The antibody blocking assay results confirm that receptor-mediated endocytosis was involved in the cell uptake of the RGD-PEGylated liposomes and the loaded siRNA. These results provide a methodology for siRNA-specific delivery to retinal pigment epithelial cells using RGD-modified PEGylated liposomes.

Acknowledgments
This research was partly supported by a National Science Council grant (99-2320-B-016-004-MY2 to C-H Chiang) and Tri-Service General Hospital (TSGH C99-086 to D-W Lu), Taiwan. We are grateful to the staff of TC5 Bio-Image Tools (Technology Commons, College of Life Science, National Taiwan University) for their assistance with confocal laser scanning microscopy and transmission electron microscopy.
