Additional index words. In vitro, explant, X-disease

Abstract. Two periwinkle cultivars, Pacific Coral (P1) and Sunstorm Rose (P2), were used for development of a plant regeneration system. Leaf and internodal explants collected from in vitro plants were plated onto woody plant medium (WPM) using a factorial arrangement of 6-benzyladenine (BA) and 1-naphthalene acetic acid (NAA). Shoots were successfully regenerated. Shoot production from leaf tissues was minimal for all cultivars, whereas internodal tissues showed variable rates of regeneration depending on the hormone combination. Cultivar P1 showed the maximum regeneration rate (73.3%) when internodal explants, 4 to 6 mm in length, were placed on WPM containing 5 μM BA and 5 μM NAA. Cultivar P2 showed a regeneration rate of 56.7% with a combination of 20 μM BA and 10 μM NAA. Shoot regeneration rate increased as the internodal explant size increased for P2; however, the regeneration rate decreased when the explant size was greater than 7 mm for P1. The shoot regeneration rate decreased as the period of the dark treatment of internodal explants increased in both P1 and P2. The antibiotics carbenicillin (Carb) and cefotaxime (Cef) had little effect on shoot regeneration. There was a slightly higher rate observed for P1 when Cef was added into the medium, whereas P2 showed a decrease with the addition of Cef. Carb showed no significant effect on shoot regeneration for both cultivars. Addition of both Carb and Cef to the medium slightly inhibited shoot regeneration.

Periwinkle (Catharanthus roseus), a member of the Apocynaceae family, is highly valued in the horticultural industry. A native to Madagascar, this herbaceous plant grows to 80 cm high and blooms continuously year-round with pink, purple, or white flowers (Hogan, 2003). Study of periwinkle has increased because of its ability to produce secondary metabolites such as terpenoid indole alkaloids that may be used to treat cardiac diseases and certain tumors in mammals (Favali et al., 2004). Periwinkle is also a natural host of many phytoplasmas. Phytoplasmas are cell wall-less organisms that infect over 300 plant species, including many woody species. They thrive in the phloem of infected plants and can cause symptoms such as curled and yellow leaves, witches-broom appearance, and phyllody, resulting in reduced crop yield and plant death (Lee et al., 2000). One phytoplasma disease, called X-disease, causes severe damage on many

Mollers and Sarkar induced calluses from in vivo plants and some callus tissues differentiated into plants on a petri dish containing MS medium (Murashige and Skoog, 1962) supplemented with 30 g L⁻¹ sucrose and 6.5 g L⁻¹ agar (#0140-01-0; Difco Co., Detroit, MI). The medium pH was adjusted to 5.7 to 5.8 before autoclaving. After growth of seedlings for 2 weeks, four shoot tips were cut and placed in 100-mL⁻¹ baby food jars containing MS medium supplemented with 2.5 μM BA and 0.5 μM gibberellic acid for shoot proliferation. All in vitro cultures were maintained in a culture room with a 16/8-h photoperiod at 21 °C and subcultured every 4 weeks.

Materials and Methods

Plant material. Seeds of two periwinkle cultivars, Pacific Coral and Sunstorm Rose, were purchased from Syngenta Seeds (Downers Grove, IL) and denoted P1 and P2, respectively. Seeds were sterilized with 70% ethanol for 2 min and a 20% bleach solution for 15 min, followed by five washes with sterile water, and then placed on filter paper in a petri dish for germination. Seedlings at the four-leaf stage were transferred to a petri dish containing MS medium (Murashige and Skoog, 1962) supplemented with 30 g L⁻¹ sucrose and 6.5 g L⁻¹ agar (#0140-01-0; Difco Co., Detroit, MI). The medium pH was adjusted to 5.7 to 5.8 before autoclaving. After growth of seedlings for 2 weeks, four shoot tips were cut and placed in 100-mL⁻¹ baby food jars containing MS medium supplemented with 2.5 μM BA and 0.5 μM gibberellic acid for shoot proliferation.

cut into 10- to 14-mm long segments. After collection was complete, explants of each cultivar and tissue type were gently mixed. The internodes were placed horizontally and the leaf segments were placed with the abaxial side up on 25 mL regeneration medium in 100 × 15-mm petri dishes sealed with parafilm and placed under a 16/8-h photoperiod at 21 °C. Each dish contained five internodal and five leaf segments and each treatment contained three dishes. This experiment was conducted as a completely randomized design (CRD) consisting of two replications of a 2 × 2 × 2 × 4 × 5 factorial arrangement with cultivars (P1 and P2), explant types (internode and leaf), PGRs (BA and NAA), and PGR concentrations (NAA at 0, 1, 5, or 10 μM and BA at 0, 1, 5, 10, or 20 μM), respectively.

2. Effect of explant size on plant regeneration. The internodes of P1 and P2 were cut into four size ranges (treatment): 1 to 3 mm, 3 to 5 mm, 5 to 7 mm, and 7 to 9 mm in length. Each treatment consisted of three dishes and 10 internodal explants per plate. The optimal regeneration medium was WPM with 5 μM NAA and 5 μM BA for P1 and 10 μM NAA and 20 μM BA for P2. The plates were sealed with parafilm and incubated in a culture room with a 16/8-h photoperiod at 21 °C. This experiment was also conducted as a CRD consisting of two replications of a 2 × 4 factorial arrangement of cultivar and explant size, respectively.

3. Effect of dark treatment on plant regeneration. Internodal explants, 4 to 6 mm in length, were placed on the optimal regeneration media described previously. Each treatment consisted of three plates and 10 explants in each plate. The plates were sealed with parafilm and placed in a dark drawer for 0-, 1-, 2-, and 3-week periods. After the dark period ended, the plates were moved to a culture room at a 16/8-h photoperiod at 21 °C. This experiment was set up as a CRD with two replications of a factorial arrangement with a 2 × 4 of cultivar and dark period, respectively.

4. Effect of antibiotics on plant regeneration. The effect of antibiotics on adventitious shoot formation was evaluated by supplementing the regeneration medium with antibiotics carbenicillin (Carb) and cefotaxime (Cef). Internodes, 4 to 6 mm in length, were plated onto the optimal regeneration media described previously. Four treatments were included in this experiment: no antibiotics, 500 mg L−1 Carb, 250 mg L−1 Carb, 250 mg L−1 Cef, and a combination of 500 mg L−1 Carb and 250 mg L−1 Cef. The effect of antibiotic was tested as a CRD consisting of two replications of a factorial arrangement with a 2 × 4 of cultivar and antibiotic treatment, respectively.

For all regeneration experiments, the number of explants producing shoots and callus size were recorded after 1 month from the beginning of the experiment. The cultures were subcultured on the fresh medium every 4 weeks and data were again recorded after the second month.

Rooting and acclimation. The response of in vitro cuttings of periwinkle to auxin (NAA) was tested. Four microcuttings (greater than 1.5 cm) were prepared from 4-week-old in vitro plants of regenerated P1 and placed into a baby food jar containing 25 mL MS medium with various concentrations of NAA. The in vitro rooting experiment was repeated twice and conducted as a CRD with three treatments: no NAA, 0.5 μM NAA, and 5.0 μM NAA. The number of cuttings rooted and the number of roots per responding cutting were recorded. The physical appearance of the roots was also noted. Rooted plants were then transplanted into a flat filled with moist Sunshine mix (Sun Gro Horticulture Canada Ltd., Seba Beach, AB, Canada) and covered with a clear plastic top for acclimation. After 1 week, the top was gradually removed and the surviving plants were potted and maintained in a greenhouse.

Statistical analysis. Data from all experiments were subject to analysis of variation and mean comparison using the GLM procedure of SAS software Version 9.1 (SAS Institute, 2004).

Results

Effects of genotype, explant, and plant growth regulator on plant regeneration. Calluses developed from both leaf and internodal explants of all cultivars when cultured on WPM with PGRs (Fig. 1A). The highest percent of callus formation (100%) occurred on the media containing both BA and NAA regardless of the concentration. As the BA concentration was lowered, callus size decreased. Lowering the ratio of BA to NAA, adventitious roots developed from both leaf and internodal explants (Fig. 1B). Leaf and internodal tissues generated callus that appeared identical in color, texture, and size. The appearance was green and dense, sometimes with very swollen explant tissue remaining. The size of callus was ≤ 4 to 9 mm in diameter during the first month; and after the second month, most calli increased to greater than 10 mm in diameter.

Analysis of variance indicated most factors were significant among P1 and P2 (Table 1). Both cultivars showed limited regeneration from leaf tissues and the regeneration rate was significantly lower than observed from internodal tissues. Significant interactions were determined among these factors except the ones among cultivar, BA, and explant.

In general, shoots were generating during the second month when explants with calluses were subcultured in the new medium (Fig. 1C). Internodal explants of both cultivars had significantly higher rates of shoot formation than those of leaf explants (Table 2).

Shoot regeneration was found to be PGR- and genotype-dependent in periwinkle (Table 2). The maximum regeneration rate (73.3%) was achieved from P1 when internodes were
placed on WPM containing 5 µM BA and 5 µM NAA, whereas 56.7% of internodal explants of P2 produced shoots on WPM with 20 µM BA and 10 µM NAA. These data indicated that determination of optimal PGR concentration was vital before conducting further experiments on shoot regeneration of periwinkle.

Effect of explant size on plant regeneration. The size of the initial internodal explant affected the regeneration rate (Fig. 2). The effect of explant size was also found to be genotype-dependent. For P1, no shoot regeneration occurred if the internode size was less than 3 mm long; however, shoot regeneration was significantly greater in 3- to 5-mm to 5- to 7-mm long explants.

Effect of dark treatment on plant regeneration. The shoot regeneration rate in both P1 and P2 was significantly lower when internode cultures were kept in the dark for a range of 1 to 3 weeks than those in the regular photoperiod (16/8 h) condition (Fig. 3). For P1, the average number of shoots regenerated per treatment decreased significantly after 1 week of dark treatment (data not shown). Two and 3 weeks in the dark completely inhibited shoot formation. P2 also showed a decrease in regeneration rate as the time of cultures in the dark increased. However, dark treatment seemed to have less effect on P2 compared with P1.

Effect of antibiotics on plant regeneration. Periwinkle cultivars P1 and P2 responded to antibiotics Carb and Cef (Fig. 4) differently; however, the difference among treatments was not significant. Addition of Cef to the plant regeneration medium increased the shoot regeneration rate from 44% to 54.5% for P1, but slightly decreased the shoot regeneration for P2 from 29% to 20%. Carbenicillin had no significant effect on shoot regeneration for both cultivars. Addition of Cef to the plant regeneration medium. In this research, leaf internode cultures in the dark increased. However, dark treatment seemed to have less effect on P2 compared with P1.

Rooting and acclimatization. In vitro cuttings of regenerated periwinkle plants rooted easily. The highest rooting rate was 100% for the shoots grown in 5.0 µM NAA and produced roots that were shorter and thicker than normal roots. In the treatment with 0.5 µM NAA, the roots formed at a rate of 90.6% and roots were healthy and strong in appearance. Approximately 47% of in vitro cuttings developed roots even in auxin-free medium. Rooted plants were transplanted in potting mix and acclimatized under ambient conditions. The regeneration rate is expressed as the percentage of explants forming shoots after 8 weeks (two subcultures) in vitro culture.

Discussion

It is well known that the balance of cytokinin and auxin in plant tissues controls the direction of organogenesis (Skog and Miller, 1957). To keep this balance ideal for development of new organs, exogenous cytokinin or auxin is usually added to the plant regeneration medium. In this research, leaf and internodal tissues of periwinkle were

*Significant at P ≤ 0.05.

Fig. 2. The effect of explant size on shoot regeneration of periwinkle cultivars ‘Pacific Coral’ (P1) and ‘Sunstorm Rose’ (P2) (P ≤ 0.05).
found to be sensitive to the presence and concentration of cytokinin and auxin. The ratio of cytokinin to auxin seemed critical for both callus and shoot regeneration. Periwinkle plants contain endogenous hormones and their effects were visible through callus production on hormone-free plants. However, the naturally occurring hormones in periwinkle tissues were not able to induce shoot formation. Addition of exogenous PGRs to the medium was necessary for plant regeneration. Addition of antibiotics to the medium was necessary for plant regeneration. Few other studies have been published examining the effect of explant size on shoot formation. Explant size may correlate to age, because the largest internodes (7 to 9 mm) were mostly obtained from the mid to bottom sections of the stem. Nhu et al. (2007) reported that as the bud age of gerbera increased, the regeneration capability significantly increased. The researchers cited that not only was the physiological state different between the buds, but the size probably played some role because the larger tissues had more nutrient reserves, which can promote more shoot development (Nhu et al., 2007).

Keeping the explants in the dark enhanced organogenesis. This result correlates with a previous study that found internodal tissues to be best suited for regeneration of Catharanthus (Mollers and Sarkar, 1989). The effect of explant size showed a controversial result in this research. Few other studies have been published examining the effect of explant size on shoot formation. Explant size may correlate to age, because the largest internodes (7 to 9 mm) were mostly obtained from the mid to bottom sections of the stem. Nhu et al. (2007) reported that as the bud age of gerbera increased, the regeneration capability significantly increased. The researchers cited that not only was the physiological state different between the buds, but the size probably played some role because the larger tissues had more nutrient reserves, which can promote more shoot development (Nhu et al., 2007).

In conclusion, an efficient regeneration system through organogenesis using vegetative tissues was developed. Effects of several factors, including genotype, explant (type and size), antibiotics, and dark treatment, on plant regeneration of periwinkle were elucidated, which will largely facilitate developing an efficient and universal genetic transformation system for periwinkle species.
