ARTICLE

Sperm-inherited H3K27me3 impacts offspring transcription and development in C. elegans

Kiyomi Raye Kaneshiro¹, Andreas Rechtsteiner¹ & Susan Strome¹

Paternal epigenetic inheritance is gaining attention for its growing medical relevance. However, the form in which paternal epigenetic information is transmitted to offspring and how it influences offspring development remain poorly understood. Here we show that in C. elegans, sperm-inherited chromatin states transmitted to the primordial germ cells in offspring influence germline transcription and development. We show that sperm chromosomes inherited lacking the repressive histone modification H3K27me3 are maintained in that state by H3K36me3 antagonism. Inheritance of H3K27me3-lacking sperm chromosomes results in derepression in the germline of somatic genes, especially neuronal genes, predominantly from sperm-inherited alleles. This results in germ cells primed for losing their germ cell identity and adopting a neuronal fate. These data demonstrate that histone modifications are one mechanism through which epigenetic information from a father can shape offspring gene expression and development.

Here is growing awareness that development and health are influenced by epigenetic information passed from parents to offspring\(^2\). The gametes, sperm and oocyte, are the conduits through which epigenetic information is passed from one generation to the next. Investigating epigenetic inheritance via the maternal line is complicated by the many non-epigenetic factors the oocyte provides to the embryo\(^1\). For this reason, the field of epigenetic inheritance largely focuses on transmission via sperm. DNA methylation and non-coding RNAs (ncRNAs) are epigenetic carriers that are transmitted by sperm to the embryo and that have been shown to influence gene expression in offspring\(^3\). Modified histones can also be passed, but their role in intergenerational and transgenerational epigenetic inheritance is less clear. In mammals, the sperm genome is primarily packaged with protamines and, while there is current debate about the advantage of features of \(C.\) \(elegans\) to tackle this issue. We previously showed that \(C.\) \(elegans\) sperm retain nucleosomes and histone marking genome-wide\(^{11}\) and that \(C.\) \(elegans\) Polycomb Repressive Complex 2 (PRC2) maintains inherited states of H3K27me3 during embryogenesis\(^{12}\). In wild-type embryos H3K27me3 is enriched over genes that were silent in the parental germline\(^{13,14}\). H2K27me3 marking inherited from hermaphroditic parent worms is essential for germline development in offspring, since hermaphroditic parents lacking PRC2 generate offspring in which the primordial germ cells die during early larval development\(^{15}\). We thus hypothesize that transmission of chromatin states from parent germ cells via sperm and oocyte to the nascent germ cells in offspring protects germline-appropriate gene expression patterns in the developing and adult germline.

In this work we investigate how chromatin states inherited from parents are maintained in offspring and whether inherited states are important for offspring transcription and development. We elucidate a mechanism through which an inherited H3K27me3(−) state is propagated from parent germ cells (sperm) to offspring germ cells. We show that inheriting a sperm genome lacking the repressive mark H3K27me3 results in derepression of many genes for somatic development, especially neuronal genes, in offspring germlines. This results in germ cells that in a sensitized genetic background lose their germ cell identity and adopt a neuronal fate. Taken together, these findings establish a cause–effect relationship between sperm-inherited histone marks and offspring transcription and development in \(C.\) \(elegans\).

### Results

#### Maintenance of an inherited H3K27me3(−) state requires MES-4.

When \(C.\) \(elegans\) embryos inherit some chromosomes with and some chromosomes without H3K27me3, PRC2 maintains inherited states by (1) restoring levels of H3K27me3 on H3K27me3(+) chromosomes after DNA replication and (2) failing to de novo methylate H3K27me3(−) chromosomes\(^{12}\). The ability of PRC2 to restore levels of H3K27me3 after genome duplication is likely explained by the EED subunit of PRC2 (MES-6 in worms) binding to H3K27me3 and stimulating the methyltransferase activity of the EZH2 subunit (MES-2 in worms)\(^{16,17}\). How PRC2 is prevented from de novo methylating chromosomes inherited lacking H3K27me3 is less clear. One possibility is that chromosomes lacking H3K27me3 are unable to recruit and stimulate PRC2 activity. Another possibility is that these chromosomes bear an opposing mark that antagonizes PRC2 activity. Likely candidates for antagonizing PRC2 activity are histone marks associated with gene expression, hereafter referred to as active marks, and their corresponding histone modifiers\(^{18,19}\).

To test if active marks prevent PRC2 from de novo methylating sperm-inherited H3K27me3(−) chromosomes during early embryogenesis, we monitored sperm chromosomes through rounds of cell division in embryos lacking a maternal load of MES-4 or SET-2, which generate the active marks H3K36me2/3\(^{20}\) and H3K4me2/3\(^{21}\), respectively. We generated embryos that inherited H3K27me3(+) oocyte chromosomes and H3K27me3(−) sperm chromosomes by mating wild-type females with PRC2 mutant males (Fig. 1a). To increase the likelihood that sperm chromosomes completely lacked H3K27me3, we used PRC2 mutant males whose parents also lacked PRC2. We call the offspring of wild-type mothers and PRC2 mutant fathers K27me3\(^{+}\)P− (M+ for maternal H3K27me3(+), P− for paternal H3K27me3(−)). We assessed whether sperm-inherited chromosomes retained the H3K27me3(−) state or acquired H3K27me3, by tracking the status of H3K27me3 on sperm-inherited chromosomes during early embryogenesis. To facilitate analysis of sperm vs. oocyte chromosomes, we performed this analysis in a temperature-sensitive \(plk-1\) mutant background that keeps sperm-inherited and oocyte-inherited chromosomes in separate nuclei for many divisions\(^{42}\) (Fig. 1b).

In all 2-cell K27me3 M+P− \(plk-1\) embryos, we observed that one nucleus in each cell contained all H3K27me3(+) chromosomes (sperm-inherited) and the other nucleus contained H3K27me3(−) chromosomes (sperm-inherited). In control and SET-2-lacking embryos, this pattern persisted in all cells during the early divisions and in the P lineage (germ lineage) throughout embryogenesis (Fig. 1c, d, Supplementary Fig. 1). In contrast, in embryos depleted of MES-4, we observed gradual acquisition of H3K27me3 on the entire set of sperm chromosomes (Fig. 1c, Supplementary Fig. 1). To assess the appearance of H3K27me3 on sperm chromosomes, we analyzed K27me3 M+P− embryos from mothers that were either mutant or wild type for \(mes-4\) (see methods). At the 1-cell stage, all K27me3 M+P− embryos examined contained sperm chromosomes lacking detectable H3K27me3 irrespective of maternal MES-4 (\(n = 6\) with maternal H3K27me3− and \(n = 4\) without maternal MES-4). In the presence of maternal MES-4, this state was maintained in all embryos up to the 4-cell stage (\(n = 21\)) and in most embryos up to the 40-cell stage (\(n = 15/19\)). In the absence of maternal MES-4, all 2-cell embryos examined acquired some H3K27me3 on sperm chromosomes (\(n = 6\)). The levels of H3K27me3 on sperm and oocyte chromosomes became indistinguishable in embryos by the 4-cell stage (\(n = 4\)) and at later stages (\(n = 15\)). This gradual acquisition of H3K27me3 matches the gradual loss of H3K36me3 in the absence of maternal MES-4\(^{33}\). Thus, MES-4 inhibits PRC2 activity, presumably through MES-4-mediated methylation of H3K36, to maintain the paternal H3K27me3(−) state. These findings show that the H3K27me3(−) state is maintained by opposing PRC2 activity with active marks and also suggest that PRC2 does not require H3K27me3 to seed its activity, as observed in mouse embryonic stem cells\(^{24}\).

#### Sperm chromatin states shape transcription in offspring

Do gamete-inherited chromatin states influence gene expression in offspring? This is a burning question in the field and one that remains elusive, in part because it is difficult to determine cause versus consequence when comparing chromatin states with transcriptional status. To establish a cause–effect relationship
Fig. 1 Maintenance of an inherited H3K27me3(−) chromatin state depends on antagonism of PRC2 by MES-4. a Diagram showing the cross between wild-type PRC2(+) K27me3(+) females and mes-3/mes-3 PRC2(−) K27me3(−) males that generates K27me3 M+P− F1 offspring. Maternal and paternal pronuclei are shown in the F1 1-cell embryo. The 2 primordial germ cells (PGCs) are shown in the newly hatched F1 larva. F1 hermaphrodites self-cross to produce F2 offspring. Figures that analyzed each generation/stage are indicated in parentheses. M, maternal; P, paternal; *Sensitized genetic background. Hybrid F1s were generated by mating Hawaii mothers with Bristol fathers. b Images of wild-type 2-cell embryos (left panels) or plk-1 2-cell embryos (right panels) demonstrate that the H3K27me3(−) state of sperm chromosomes in K27me3 M+P− embryos (bottom panels) is easily monitored when sperm- and oocyte-inherited chromosomes are kept in separate nuclei in plk-1 mutants. DAPI-stained DNA in red. H3K27me3 immunostaining in green. Scale bar represents 10 μm. c 2-cell and 8-cell stage K27me3 M+P− embryos whose mothers were fed empty vector RNAi (control) or mes-4(RNAi) to knock down the maternal load of MES-4. Scale bar represents 10 μm. d Somatic cells and PGCs in a K27me3 M+P+ L1 (left) and a K27me3 M+P− L1 (right). L1 schematics show the observed staining pattern in PGCs for each genotype. DAPI-stained DNA in red. H3K27me3 immunostaining in green. Scale bar represents 2 μm.
between inherited chromatin and offspring transcription requires that (1) genetically identical individuals display different transcriptional outcomes as a result of inheriting different chromatin states, (2) transcriptional changes must be demonstrated to occur in cis, thus eliminating alternative epigenetic carriers that function in trans (e.g., cytoplasmic ncRNAs), and (3) DNA methylation, which also functions in cis, must be eliminated as a potential mediator of the observed transcriptional changes. We met the third criterion by using the model system *C. elegans*, which lacks canonical DNA methylation. We met the remaining criteria by comparing transcription from sperm-inherited and oocyte-inherited alleles in genetically identical (hybrid *fem-2::*; *mes-3*/*+) worms (Fig. 1a) that inherited the sperm genome with or without H3K27me3, which we call K27me3 M+P+ and K27me3 M+P−.

We showed previously that K27me3 M+P− embryos have different chromatin states on their sperm-inherited and oocyte-inherited genomes and that those states are maintained in all cells of early embryos12. As embryos develop, the gamete-inherited chromatin states are rewritten in somatic cells but maintained through the two cell divisions that generate the primordial germ cells (PGCs) present in newly hatched larvae12 (Fig. 1d). When newly hatched larvae begin to feed, the PGCs launch their transcriptional program and begin to proliferate. During larval development, H3K27me3 gradually begins to accumulate on sperm-inherited chromosomes12. Absence of H3K27me3 on sperm chromosomes at the onset of germ cell transcription could result in the activation of inappropriate genes. Once activated, a euchromatic state could be propagated at specific loci, sensitizing daughter germ cells to continued expression of inappropriate genes and potentially downstream target genes. We investigated whether global differences in inherited chromatin states in PGCs impact transcription in the developing germline. We used single-nucleotide polymorphisms (SNPs) between parental strains (from Bristol, England, and from Hawaii) to compare transcription from sperm-inherited and oocyte-inherited genomes. This allowed us to determine whether transcriptional changes occurred in cis (from sperm alleles specifically) or in trans (from both sperm and oocyte alleles).

Worms that inherited sperm chromosomes lacking H3K27me3 misexpressed genes in their germlines; 149 genes were upregulated and 116 genes were downregulated (FDR < 0.1) in K27me3 M+P− compared to K27me3 M+P+ worms (Fig. 2a, Supplementary Figs. 2, 3). Of the genes that were upregulated in K27me3 M+P− germlines, 96% are enriched for H3K27me3 in wild-type sperm11 (Supplementary Fig. 4). While K27me3 M+P− worms were typically fertile, they generated a significant proportion of sterile offspring (Fig. 2b). These findings demonstrate that altering sperm-inherited chromatin states results in changes to germline transcription and function.

Expression of genes assessed by reads overlapping SNPs between Bristol and Hawaii correlated well with expression assessed by using all reads mapping to a gene (Supplementary Fig. 3a). Therefore, we could use SNPs to determine, for the 23% of misexpressed genes that contain a SNP, if transcription differences arose from the sperm allele, the oocyte allele, or both (Supplementary Data 1). Our analysis of SNP-containing transcript reads indicated that downregulated genes reflect decreased transcription from both the sperm and oocyte allele. However, upregulated genes reflect increased transcription primarily from the sperm allele (Fig. 2c, d). Importantly, approximately half of these genes were upregulated in cis with increased transcription from the sperm allele specifically (dark red triangles in Fig. 2c). These findings demonstrate that differential marking on sperm-inherited and oocyte-inherited genomes allows sperm-inherited and oocyte-inherited alleles within the same cell to achieve different transcriptional outcomes in offspring. Given that *C. elegans* lacks canonical DNA methylation, this finding establishes a causal role for sperm-inherited H3K27me3 in regulating transcription in offspring. It also raises the possibility that environmentally induced changes to gamete marking could lead to transcriptional changes in offspring, with developmental consequences.

The genes upregulated from both sperm and oocyte alleles likely represent downstream targets of an initially misexpressed factor(s). The observation that these genes are more upregulated from sperm alleles than oocyte alleles led us to hypothesize that the presence of H3K27me3 on the oocyte genome acts as a barrier against transcriptional activation of germline-inappropriate genes. H3K27me3 on the oocyte-inherited genome would not be expected to protect it from factors that would shut down expression of germline-appropriate genes. This may explain the observation that downregulated genes were downregulated from both sperm and oocyte alleles. This led us to wonder if the global pattern of misexpression resulting from altered sperm chromatin was a concerted deviation from a germline program. To explore this, we performed gene ontology analysis on upregulated and downregulated genes. We found that downregulated genes are enriched for genes involved in reproduction and that upregulated genes are enriched for genes involved in somatic development, especially neuronal development (Supplementary Fig. 2b, c). This suggests that K27me3 M+P− germlines are deviating from a germline program of gene expression toward a somatic program, perhaps favoring a neuronal program.

**Sperm-inherited H3K27me3 protects germ cell fate in offspring.** To test whether germlines in K27me3 M+P− worms that inherited altered sperm chromatin are in fact transitioning toward a neuronal fate, we analyzed worms carrying a pan-neuronal reporter gene, unc-119::GFP. We compared expression of this reporter in genetically identical worms that inherited sperm chromatin with either a wild-type pattern of H3K27me3, K27me3 M+P+, or lacking H3K27me3, K27me3 M+P−. As noted above, K27me3 M+P− and K27me3 M+P+ worms are fertile; we observe that fertile germlines do not detectably express *unc-119::GFP (n > 500)* nor do they significantly upregulate *unc-119* transcript. Performing this analysis in a sensitized genetic background in which the maternal load of PRC2 was reduced by half (mes-3/*+* heterozygous mother) rendered ~30% of K27me3 M+P− worms sterile (*n = 267/894*); <0.3% of K27me3 M+P+ worms were rendered sterile (*n = 2/870*). In this background, we found that the *unc-119::GFP* neuronal reporter was expressed in a significant percentage of sterile K27me3 M+P− adult germlines (Supplementary Table 1). Notably, expression of the neuronal reporter increased with age, from 16% in sterile day 1 adults to 31% in sterile day 2 adults. Expression of the neuronal reporter was rarely detected (<0.1%) in germlines from late-stage larva (L4) (*n = 1/146*) and never observed in the germlines from the rare sterile K27me3 M+P+ worms. These findings indicate that deviation from a germline program in K27me3 M+P− worms is progressive and strongly suggest that loss of H3K27me3 from the sperm-inherited genome results in a failure to maintain germ cell identity rather than a failure to establish it.

To test whether neuronal genes are derepressed from endogenous loci in K27me3 M+P− germlines, we stained UNC-119::GFP(+) K27me3 M+P− germlines for UNC-64, a neuronally expressed plasma membrane protein involved in synaptic vesicle fusion16. We detected this protein in all of the germlines analyzed (*n = 6*) (Fig. 3c). To test for loss of expression of genes involved in reproduction, we stained sterile K27me3
M+P− germlines for the germline proteins PGL-1 (a component of germ granules) and HTP-3 (a component of the synaptosomal complex). We found that PGL-1 and HTP-3 were below detection (or nearly so) in 100% (n = 27) and 28% (n = 60) of sterile K27me3 M+P− germlines analyzed, respectively, regardless of whether or not they expressed the neuronal GFP reporter (Fig. 3d, e). Although only 28% of sterile K27me3 M+P− germlines lacked detectable HTP-3 staining, the remaining 72% of germlines analyzed displayed abnormal HTP-3 patterns (Fig. 3d). Of note, germlines expressing the neuronal UNC-119::GFP reporter consistently displayed more severe HTP-3 phenotypes than germlines that were UNC-119::GFP(−) (Fig. 3d).

Consistent with K27me3 M+P− germlines adopting a neuronal identity, we readily observed patches of highly concentrated GFP signal in UNC-119::GFP(+) germlines, indicating that the normally syncytial germ cells had cellularized. In some cases, we observed axo-dendritic structures emanating from these bright GFP(+) cells (Fig. 3b, c). Our findings demonstrate that absence of H3K27me3 from the sperm-inherited genome results in the derepression of many somatic genes, especially neuronal genes, predominantly from sperm-inherited alleles. In a sensitized background, lack of H3K27me3 on the sperm-inherited genome results in the derepression of many somatic genes, especially neuronal genes, predominantly from sperm-inherited alleles. In a sensitized background, lack of H3K27me3 on the sperm-inherited genome results in the derepression of many somatic genes, especially neuronal genes, predominantly from sperm-inherited alleles. In a sensitized background, lack of H3K27me3 on the sperm-inherited genome results in the derepression of many somatic genes, especially neuronal genes, predominantly from sperm-inherited alleles.
these processes can lead to severe developmental defects and gene expression patterns and thus protect cell identity. Defects in differentiation of different lineages. During aging, established chromatin states must be rewritten to enable differentiation of different lineages. During early development, establishment and maintenance of chromatin states are critical for the establishment and/or maintenance of cell fates in those offspring. Because we observe reprogramming of germ cells toward neuronal cells in adult K27me3 M+P− germ lines but only rarely in larval K27me3 M+P− germ lines, we conclude that offspring germ cells lose rather than fail to establish their germ cell identity. These findings reveal that in worms, sperm-inherited H3K27me3 is transmitted to offspring germ cells to prevent germ-line-inappropriate transcription and thus protect germ cell identity.

Fig. 3 Inheritance of sperm chromosomes lacking H3K27me3 causes germ cells in offspring to transition toward a neuronal fate. a Immunofluorescence images of a sterile germ line from a K27me3 M+P− worm in a sensitized genetic background (see text) and carrying an unc-119::gfp reporter transgene. cancer. Whether chromatin states established in the parent and transmitted to offspring via sperm or oocyte influence the establishment and/or maintenance of cell fates in those offspring is a critical question in the field. Our findings demonstrate that in C. elegans sperm-inherited chromatin states influence germ cell identity in offspring. Because we observe reprogramming of germ cells toward neuronal cells in adult K27me3 M+P− germ lines but only rarely in larval K27me3 M+P− germlines, we conclude that offspring germ cells lose rather than fail to establish their germ cell identity. These findings reveal that in worms, sperm-inherited H3K27me3 is transmitted to offspring germ cells to prevent germ-line-inappropriate transcription and thus protect germ cell identity.

Altogether, our findings point to a model in which gamete-inherited patterns of H3K27me3 act as a barrier to inappropriate transcription; in germ cells, this barrier function is particularly important in suppressing transcription of factors that could drive germ cells toward alternative cell identities (Fig. 4). In the germlines of worms that inherited the sperm genome lacking H3K27me3, we speculate that some genes become upregulated as a direct result of diminished H3K27me3 (Factor X in Fig. 4), while other genes may be upregulated as a consequence of being the target of an upregulated gene. An alternative scenario is that Factor X genes are normally expressed in wild-type germ cells but prevented from activating germ-line-inappropriate target genes by H3K27me3 on those target genes. An example of the first scenario (Fig. 4) is the vab-7 gene, which encodes a neuronal transcription factor28; vab-7 is not expressed in wild-type germ lines but becomes upregulated in K27me3 M+P− germlines. Examples of the alternative scenario are genes that encode neuronal specification factors (e.g., dic-1 and nsy-7)28 that are highly expressed in both wild-type and K27me3 M+P− germlines. Regardless of the exact cascade of gene activation, our expression analysis of K27me3 M+P− germlines suggests a programmatic shift toward a neuronal program and supports the hypothesis that an upstream factor(s) is altering gene expression in a concerted manner, especially from the H3K27me3-depleted sperm genome.

Our findings establish a causal role for sperm-inherited histone marks influencing transcription in offspring and reveal their role in protecting cell identity. Together with observations that in mammals, sperm retain modified histones over developmentally important genes5–7, this work implicates sperm-inherited chromatin states as one mechanism through which environmentally
Sperm-inherited alleles are similarly marked with H3K27me3. SS1298 set-2(bn129) fem-2(b244ts) III.

Fixing and staining embryos, larvae, and germlines. Specimens were flattened between a slide and a coverslip by wicking away buffer (see below). Slides were frozen in liquid nitrogen, coverslips were removed, then slides were fixed in methanol (10 min) and acetone (10 min) and allowed to air dry for up to 3 days. Slides were blocked (1.5% ovalbumin, 1.5% BSA in PBS) for 25 min, then incubated with primary antibodies overnight at 4 °C. Slides were washed 3× in PBST (0.1% tween in phosphate buffered saline pH 7.2), blocked for 5 min, incubated with secondary antibodies and DAPI at room temperature for 2 h, and washed 3× in PBST. Coverslips were mounted on slides with gelutol. Slides were allowed to dry for up to 3 days before being imaged.

**Antibodies.** Primary antibodies and their dilutions were as follows: 1,300,000 of 2.45 mg/mL mouse anti-H3K27me3 (Kimura mAb E7 clone CMA323, Wako cat#399-95259), 1,300 original stock solution of rabbit anti-H3K27me3 (C56B11 Cell Signaling MAb#9733 lot#C36B11), 1:4000 of 0.4 mg/mL mouse anti-GFP (Roche cat#11 814 460 001 lot#14158300), 1:4000 rabbit anti-UNC-64 serum. 1:50,000 rabbit anti-PGL-1 serum, 1:500 guinea pig anti-HTP-3 serum. Secondary antibodies conjugated to Alexa Fluor: 488 goat anti-mouse (Life cat#11011), 488 goat anti-rabbit (Life cat#11012), and 594 goat anti-guinea pig (Molecular Probes cat#A11676) were used at 1:300 with 0.05 µg/mL 4',6-diamidino-2-phenylindole (DAPI).

**Microscope set-up for immunocytochemistry.** All images were acquired using the following: Yokogawa CSU-11 spinning disk scanner, Nikon (Garden City, NY) TE2000U inverted stand, Hamamatsu IM-X2 camera, solid state camera 488, 494, 556, and 561 nm laser lines, 435–485, 500–550, and 573–613 fluorescent filters, Nikon Plan Apo VC 60×/1.40 oil objective, Nikon Plan Apo 100×/1.40 oil objective, and Micro-Manager software.

**Analysis of MES-4-depleted and SET-2 mutant embryos.** plk-1; fog-1 unc-11 females (Fig. 1b, c) or fem-2(1ts) or set-2 fem-2(1ts) females (Supplementary Figure 1) were mated to N2 (P+) or mes-3 M-Z; him-8 (P+) males (M- for no maternal load of MES-3, Z- for no zygotic synthesis of MES-3) on plates with mes-4 RNAi, empty vector RNAi, or OP50 (Supplementary Figure 1c) and incubated overnight at 23 °C (Fig. 1b, c) or 20 °C (Supplementary Figure 1). Embryos were dissected from mated females in egg buffer (25 mM HEPES pH 7.4, 118 mM NaCl, 48 mM KCl, 2 mM CaCl2, 2 mM MgCl2) with 1 mM levamisole on polylysine-coated slides. Embryos attached to slides were fixed and stained as described above. Stacks of optical sections were acquired on a Solamere spinning disk confocal system as described above. Stacks were collapsed into maximum intensity projections using Micro-Manager. Single-channel and merge images were generated in Photoshop. To assess the appearance of H3K27me3 on sperm chromosomes in embryos with and without a maternal load of MES-4, optical sections of K27me3 M+P- embryos from fem-2(1ts) mothers (with a maternal load of MES-4) or from fem-2(1ts); mes-4(b737) mothers (lacking a maternal load of MES-4) were stained for DNA and H3K27me3 and scored for: 1) undetectable H3K27me3 on some chromosomes, 2) reduced levels of H3K27me3 on some chromosomes relative to control chromosomes, or 3) indistinguishable levels of H3K27me3 on all chromosomes.

**Analysis of K27me3 M+P- and M+P+: L1 larvae.** fem-2(tts) females were mated to either mes-3/H2-GFP, unc-119 (P+) or mes-3 M+Z-; unc-119 (P-) males for ~48 h. Gravid females were transferred to 100 µL S Basal (5.85 g NaCl, 1 g K2HPO4, 6 g KH2PO4, 1 mL cholesterol (5 mg/mL in ethanol), H2O to 1 L) on gelatin chrom atom-coated slides and incubated overnight in a humid chamber at 20 °C. Starved K27me3 M+P- M+P+ larvae were pollysine-coated slides. L1s attached to slides were fixed and stained as described above. Stacks of optical sections were acquired on a Solamere spinning disk confocal system as described above. Stacks were collapsed into maximum intensity projections using Micro-Manager. Single-channel and merge images were generated in Photoshop.

**Analysis of sensitized K27me3 M+P- and M+P+: germlines.** mes-3/H2-GFP; fem-2(tts) females were mated to either mes-3/H2-GFP, unc-119 (P+) or mes-3 M+Z-; unc-119 (P-) males to generate K27me3 M+P- and K27me3 M+P+ worms, respectively. 146 L4 K27me3 M+P- larvae were cut at the pharynx to extrude their anterior germline for assessment of UNC-119; GFP expression in germ cells. Sterile adults on day 1 of adulthood (n = 267) were moved to new plates for live analysis to determine whether germ cells expressed UNC-119;GFP. Sterile day 1 adults that lacked germine expression of UNC-119;GFP were allowed to age at 20 °C for a repeat analysis of UNC-119;GFP expression in germ cells on day 2 of adulthood. L4s, day 1 sterile adults, and day 2 sterile adults were analyzed for germ cell expression of UNC-119;GFP on a Leica MZ16F microscope equipped with a GFP filter. Germlines were imaged for GFP expression both by live imaging of whole worms and by fixing dissected germlines in egg buffer with 1 mM levamisole and 0.5% tween on pollysine-coated slides and immunostaining for GFP, UNC-64, PGL-1, and/or HTP-3. Stacks of optical sections were acquired on a Solamere spinning disk confocal system controlled by Micro-Manager software as described above. Stacks were collapsed into maximum intensity projections using Micro-Manager and stitched together into composite images using Photoshop. Single-channel and merge images were generated in Photoshop. In some cases (Fig. 3c), germlines were straightened using ImageJ.

**Sterility analysis of K27me3 M+P- and M+P+: offspring.** fem-2(tts) females were mated to mes-3/H2-GFP, fem-2(tts) or mes-3 M+Z-; fem-2(tts) males at 15 °C, mes-3/+; fem-2 K27me3 M+P+ and M+P+. L4s (n = 30 replicate 1; n = 40 replicate 2) were cloned to individual plates and allowed to lay eggs for ~24 h, then transferred to fresh plates each day until no more embryos were laid. Embryos from K27me3 M+P- and M+P+ hermaphrodites were incubated at 15 °C until day 1 adulthood, then hermaphrodites were scored as sterile (no embryos in the uterus) or fertile (n = 9370 replicate 1; n = 9693 replicate 2).
males (P−) to generate genetically identical mes-3/+; fem-2/+; him-8/+; K27me3 M−P+/+ and M−P− offspring, respectively. In addition, feminized fem-2 (CB4856 background) males were mated to wild-type N2 males to generate "wild-type" hybrid offspring. mes-3/+; fem-2/+; him-8/+; K27me3 M−P−; and M−P− ("wild-type" hybrid) L4 offspring were picked and allowed to age overnight to generate K27me3 M−P+/+, K27me3 M−P−, and "wild-type" hybrid 1 day adults. ∼50 germlines were dissected from day 1 adults in egg buffer with 1 mM levamisole, 0.5% tween and transferred into 300 μL of ice-cold TRIZol reagent (Life Technologies), then stored at −80 °C. Samples were subjected to 3 freeze-thaw cycles. One microliter linear polyacrylamide was added to each sample, vortexed, then transferred to Phase Lock Gel-Heyacold 2 mL tubes to extract the aqueous phase. 0.75 volume isoamyl alcohol was added to each sample and incubated overnight at −20 °C. RNA was isolated via ethanol precipitation and rehydrated in 14.5 μL RNase-free H2O. 2.5 μL were used to assess RNA quality (Agilent RNA Nano Bioanalyzer Chip) and concentration (Qubit Quant-IT RNA Assay Kit). The remaining 12 μL were depleted of RNA (NEBNext RNA Depletion Kit) and used for library preparation (NEBNext Ultra RNA Library Prep Kit). Libraries were sequenced on an Illumina HiSeq4000 to acquire paired-end 100 bp reads.

Processing and analyzing RNA-seq data. For differential expression analysis, raw sequences were mapped to transcriptome version WS220 using TopHat239. Only reads with one unique mapping were allowed. Otherwise default options were used. Reads mapping to ribosomal RNAs were removed from further analysis. HTSeq40 was used to obtain read counts per transcript. DESeq237 was used to determine differentially expressed genes from HTSeq counts. A Benjamini-Hochberg multiple-comparison corrected value cutoff of 0.1 was used as a significance threshold to identify significantly differentially expressed genes between K27me3 M−P− and M−P+ germlines.

To identify RNA-sequencing (RNA-seq) reads coming from the Hawaiian or Bristol parent in the hybrid offspring germlines, the annotated single nucleotide polymorphisms (SNPs) of the Hawaiian strain CB4856 genome compared to the Bristol strain n2 WS220 genome were downloaded from WormBase. 126,615 unique SNPs were downloaded, of which 25,980 SNPs mapped to an exon in a total of 9,146 coding genes, according to WormBase. Henceforth, we refer to these SNPs as exonic SNPs.

RNA-seq reads from the Bristol strain, Hawaiian strain, and hybrids were mapped to the Bristol (N2) genome version WS220 using TopHat2, once allowing 1 mismatch in a read and a second time not allowing a mismatch. Reads overlapping exonic SNP positions were identified, and HTSeq was used to count these SNP-containing reads for each transcript. Counts per transcript were normalized by the number of total transcript reads, including non-SNP-overlapping reads, for each of the libraries sequenced. An average count per transcript was obtained by averaging the replicates for each of the Bristol, Hawaiian, and hybrid K27me3 M−P− and M−P+ replicate experiments. A further quality control step was imposed. For the Bristol and Hawaiian RNA-seq data, we calculated the fraction of reads that mapped both to the matched and mismatched sequence for each transcript. For each transcript in the Hawaiian RNA-seq data, a score h2 was calculated: h2 = (hm1−1 + hm0)/(hm1 + hm0), where hm1 and hm0 denote the normalized read counts for transcript i from mapping with a mismatch 1 and with a mismatch 0 to the Bristol genome, respectively. In the same way, we defined h2 for the hybrid. A read was regarded as a hybrid reads when it had a mismatch compared to the Bristol genome. For Hawaiian transcript reads from exonic SNPs, we expect h2 to be close to 1; all reads should have mapped when allowing 1 mismatch, and none should have mapped when allowing no mismatches. For Bristol transcript reads from exonic SNPs, we expect h2 to be close to 0, as the number of reads from both mappings should have been very similar. We removed transcripts that did not follow these requirements. If a transcript i had a h2 < 0.75 for the Hawaiian RNA-seq data, or an absolute value |h2| > 0.25 for the Bristol RNA-seq data, that transcript was removed from further analysis. These requirements removed 1080 transcripts with exonic SNPs. For the remaining 8066 transcripts we obtained from the hybrid K27me3 M−P− and M−P+ RNA-seq data, we determined the transcript reads from the sperm allele (Bristol) as reads that mapped when allowing 0 mismatches. We determined the transcript reads from the oocyte allele (Hawaiian) as reads that mapped when allowing 1 mismatch but that did not map when allowing 0 mismatches. We thus calculated transcript reads from the oocyte allele by subtracting reads that mapped when allowing 0 mismatches (sperm allele reads) from reads that mapped when allowing 1 mismatch (reads from both gamete alleles).

Many genes with exonic SNPs were not expressed in any of our germline RNA-seq data. We filtered out these non-expressed transcripts from further analysis by requiring that at least one condition, K27me3 M−P− or M−P+, be at least 0.5. Because our goal was to use SNP-containing transcript reads as a proxy for total transcript reads, we filtered out transcripts that had a greater than 2.5-fold difference between the log of SNP-containing reads versus the log of total reads for a given transcript in hybrid samples (Hawaiian mother and Bristol father). This requirement removed 190 genes and left 2,606 transcripts for further analysis. To avoid dividing by zero when calculating log fold changes and to reduce the effect of noise on low read counts, we added a pseudo-count of 0.5 to all remaining transcripts from oocyte alleles and sperm alleles in both conditions.

GO analysis of significantly misregulated genes. Significantly upregulated genes (361 genes) and downregulated genes (342 genes) in the "wild-type" hybrid vs K27me3 M−P− comparison (FDR < 0.05) were used to perform GO analysis (Supplementary Fig. 2b, c). GO analysis was performed using the tissue enrichment tool provided with WormBase (version WS266).

Statistics. Sample sizes and statistical tests used are described in the figure legends. Paired student’s t-tests and Wilcoxon rank sum tests were performed using R. Four biological replicates of sequencing data were used. No replicates were omitted. Differential expression analysis was performed using DESeq2, which uses negative binomial generalized linear models. Adjusted p-values were calculated using the Benjamini-Hochberg method performed by DESeq2.

Reporting Summary. Further information on experimental design is available in the Nature Research Reporting Summary linked to this article.

Data availability

Raw sequence files and processed data sets generated in this study are available at the Gene Expression Omnibus (GEO) repository, accession GSE123415. Processed data sets available at GEO are as follows: RNA-seq read counts for K27me3 M−P−, K27me3 M−P+ and "wild-type" hybrid containing (1) all read counts mapping to a transcript, (2) read counts overlapping SNPs mapped to the Bristol genome allowing 1 mismatch (Hawaiian & Bristol), (3) read counts overlapping SNPs mapped to the Bristol genome allowing 0 mismatches (Bristol-specific reads), (4) differential expression analysis comparing transcript reads from K27me3 M−P− vs. M−P+, and (5) differential expression analysis comparing transcript reads from K27me3 M−P− vs. "wild-type" hybrid. Supplementary Data 1 consists of sperm-specific and oocyte-specific reads and the log, fold changes between K27me3 M−P− and M−P+ for significantly misregulated SNP containing genes. All other relevant data supporting the key findings of this study are available within the article and its Supplementary Information files or from the corresponding author upon reasonable request. A reporting summary for this Article is available as a Supplementary Information file.
