ABSTRACT
To effectively exploit large-scale structure surveys, we depend on accurate and reliable predictions of non-linear cosmological structure formation. Tools for efficient and comprehensive computational modelling are therefore essential to perform cosmological parameter inference analyses. We present the public software package ReACT, demonstrating its capability for the fast and accurate calculation of non-linear power spectra from non-standard physics. We showcase ReACT through a series of analyses on the DGP and f(R) gravity models, adopting LSST-like cosmic shear power spectra. Accurate non-linear modelling with ReACT has the potential to more than double LSST’s constraining power on the f(R) parameter, in contrast to an analysis that is limited to the quasi-linear regime. We find that ReACT is sufficiently robust for the inference of consistent constraints on theories beyond ΛCDM for current and ongoing surveys. With further improvement, particularly in terms of the accuracy of the non-linear ΛCDM power spectrum, ReACT can, in principle, meet the accuracy requirements for future surveys such as Euclid and LSST.

Key words: cosmology: theory – large-scale structure of the Universe – methods: analytical

1 INTRODUCTION
The standard model of cosmology, based on general relativity plus a cosmological constant (Λ) and cold dark matter (CDM), has been extraordinarily successful in reproducing our cosmological observations such as the cosmic microwave background (CMB, Ade et al. 2016) and the large-scale structure of the universe (LSS, Anderson et al. 2013; Song et al. 2015; Beutler et al. 2017). The model relies on only two fundamental assumptions: that general relativity holds on all physical scales and that the Universe is homogeneous and isotropic. On the other hand, the so called ‘dark’ components, Λ and CDM, account for 95% of the matter-energy content of the Universe today.

Further, several mild tensions in cosmological parameters between late-time measurements and the CMB have been uncovered. In particular, there is a tension in the value of the Hubble parameter today, H₀, (Efstathiou 2014; Zhang et al. 2017; Riess et al. 2019; Wong et al. 2020; Lombriser 2020; Pesce et al. 2020) and in the amplitude of density fluctuations, σ₈, (Heymans et al. 2013; Hildebrandt et al. 2017; Abbott et al. 2018) from direct measurement and inferred from extrapolating from the best fit CMB data (Ade et al. 2016) (also see Lin & Ishak 2017).

Motivated by these issues, probing the nature of dark matter and dark energy, as well as testing alternatives to ΛCDM, is the main focus of modern cosmology. In particular, a plethora of exotic dark energy and modified gravity models have been proposed over the past couple of decades (for reviews see Copeland et al. 2006; Clifton et al. 2012; Joyce et al. 2016; Koyama 2018). But any viable alternative to the concordance model must pass all Solar System tests, match all cosmological data equally well and moreover, not modify the speed of gravitational wave propagation (Lombriser & Taylor 2016; Abbott et al. 2017; Lombriser & Lima 2017; Creminelli & Vernizzi 2017; Ezquiaga & Zumalacárregui 2017; Baker et al. 2017; Sakstein & Jain 2017; Battye et al. 2018; de Rham & Melville 2018; Creminelli et al. 2018). This places very tight constraints on modifications to ΛCDM in the regimes of these experiments.

One regime that still remains largely open to signals of modified gravity or dark energy is the LSS of the universe, in particular, the non-linear, small cosmological scales. It is in this regime that cosmological modifications of gravity are expected to give clear signatures as they transition to recover general relativity at Solar-System scales. Many modified gravity models generically realise...
such a transition through screening mechanisms (Vainshtein 1972; Khoury & Weltman 2004; Babichev et al. 2009; Hinterbichler & Khoury 2010). With current and future LSS surveys such as LSST\(^1\) (Chang et al. 2013), KiDS\(^2\) (Kuijken et al. 2015), DES\(^3\) (Albrecht et al. 2006), DESI\(^4\) (Aghamousa et al. 2016), HSC\(^5\) (Aihara et al. 2018) and Euclid\(^6\) (Laureijs et al. 2011), our ability to precisely measure these scales has become unprecedented and will further improve over the next decade. With this new wealth of high-precision data in the non-linear regime of cosmic structure formation, the challenge has become the accurate and efficient modelling of our observables for our theories.

In this paper, we present ReACT\(^7\), a fast and reliable code that employs the approach of Cataneo et al. (2019) to accurately compute general modifications to the non-linear ΛCDM matter power spectra for theories beyond ΛCDM. The efficiency of ReACT enables its implementation in statistical parameter inference pipelines, as typically employed by LSS surveys. We demonstrate the reliable performance of the code in a set of Markov Chain Monte Carlo (MCMC) analyses on mock LSS data sets that aim to represent future survey cosmic shear measurements. These furthermore double as preliminary analyses that investigate the importance of modelling non-linear modifications of gravity in cosmological and gravitational parameter estimation.

This paper is organised as follows: In section 2 we present the theoretical framework used to compute general modifications to ΛCDM non-linear power spectra. In section 3 we present the ReACT code, outlining its structure, performance and a useful implementation into the well established framework. We present our MCMC analyses in section 4. We summarise our results and conclude in section 5.

2 THE FRAMEWORK: HALO MODEL REACTIONS

In order to effectively exploit the high-precision data supplied by the new generation of galaxy surveys, which may reveal new physics, we rely on accurate and reliable computational tools for modelling the non-linear cosmic structure formation. Here, we are concerned with computing the non-linear matter power spectrum in a model-independent framework. In Cataneo et al. (2019), the reaction approach was introduced, providing such a framework. Its prescription for the non-linear matter power spectrum in the desired theory of dark energy or gravity, \(P_{\text{NL}}\), involves the two quantities explicit in the following equation

\[
P_{\text{NL}}(k, z) = \mathcal{R}(k, z) P_{\text{NL}}^{\text{pseudo}}(k, z).
\]

Here, \(\mathcal{R}(k, z)\) is the halo model reaction and \(P_{\text{NL}}^{\text{pseudo}}(k, z)\) is the pseudo-matter ΛCDM power spectrum. Note that all power spectra without a superscript will be assumed to be the beyond-ΛCDM spectra.

2.1 Pseudo power spectrum

The pseudo cosmology is defined as a universe with ΛCDM physics but where the initial conditions are adjusted so that the linear clustering matches that of the target beyond-ΛCDM cosmology, i.e.

\[
P_{\text{L}}^{\text{pseudo}}(k, z) = P_L(k, z),
\]

where \(P_L(k, z)\) is the linear power spectrum in the theory of interest, be it modified gravity or having an evolving dark energy component (or both). In practice this is done by rescaling the modified linear power spectrum at the target redshift to the initial redshift using the linear ΛCDM growth factor.

Modelling the non-linear pseudo power spectrum accurately is essential in obtaining percent-level accuracy in the target spectrum \(P_{\text{NL}}(k, z)\). Giblin et al. (2019) propose the development of an emulator for this quantity. In this work, we will use the halo-model based formula described in Mead et al. (2015, 2016) to give predictions for \(P_{\text{NL}}^{\text{pseudo}}(k, z)\), which is accurate at the 5%-level for \(k < 10h$/Mpc$. We note that this level of accuracy is the key limiting factor of our predictions for the target spectrum, \(P_{\text{NL}}(k, z)\), at scales \(k < 5h$/Mpc. At smaller scales, the inaccuracy of the reaction, \(\mathcal{R}\), becomes of the same order. Note that the modified linear spectrum, \(P_L(k, z)\) is computed using ReACT.

To obtain \(P_{\text{NL}}^{\text{pseudo}}(k, z)\), we provide the target modified \(P_L(k, z)\) as input for the publicly available REACT-code, which computes the halo model function of Mead et al. (2015, 2016). Further, we emphasise that the choice of the Mead et al. (2015) formula for \(P_{\text{NL}}^{\text{pseudo}}\) is an implementation detail and our framework will work for any prescription for the non-linear \(P(k)\) in ΛCDM as long as one can specify the linear clustering to the chosen framework. In other words, one can model this spectrum using any standard ΛCDM method that can be informed of the non-standard changes in the shape of the beyond-ΛCDM linear power spectrum. For more details on the pseudo spectrum we refer the reader to section 3.3 of Cataneo et al. (2019) and Giblin et al. (2019).

2.2 The reaction

The quantities ReACT computes are both \(P_L(k, z)\) and the halo-model reaction \(\mathcal{R}(k, z)\), that is specified by (Cataneo et al. 2019)

\[
\mathcal{R}(k, z) = \frac{(1 - E(z)) e^{-k/k(z)} + E(z) P_L(k, z) + P_{1h}(k, z)}{P_{1h}^{\text{pseudo}}(k, z)}.
\]

It is an ansatz for the response of a ΛCDM spectrum to modified physics, based on the halo model and 1-loop perturbation theory (see Cooray & Sheth (2002) and Bernardeau et al. (2002) for respective reviews). The different components are given as

\[
P_{1h}^{\text{pseudo}}(k, z) = P_L(k, z) + P_{1h}(k, z),
\]

\[
E(z) = \lim_{k \to 0} \frac{P_{1h}(k, z)}{P_{1h}^{\text{pseudo}}(k, z)},
\]

\[
k(z) = - \frac{1}{k} \left( \ln \left[ \frac{A(k, z)}{P_L(k, z)} - E(z) \right] - \ln \left[ 1 - E(z) \right] \right)^{-1},
\]

where

\[
A(k, z) = \frac{P_{1\text{-loop}}(k, z) + P_{1h}(k, z)}{P_{1\text{-loop}}^{\text{pseudo}}(k, z) + P_{1h}^{\text{pseudo}}(k, z)},
\]

\[
P_{1\text{-loop}}^{\text{pseudo}}(k, z) - P_{1h}(k, z).
\]
predictions for equation (3) under some specification of the back-spherical collapse modification
is sufficient for all redshifts up to the spherical collapse modifications (e.g., if we wish to employ ellipsoidal collapse, see Sheth et al. 2014). This parametrisation is explicitly specified, for the predictions are sufficiently accurate at all redshifts considered. In fact, this approach is affected by similar inaccuracies characterising the ‘screened’ 1-loop spectrum, therefore it is more suitable for fractional quantities like the reaction.

For the limit in equation (5) we take $k = 0.01 h$/Mpc which is sufficient for all redshifts up to $z = 0$. For the scale at which we compute $k_*$, we choose $k = 0.06 h$/Mpc following Cataneo et al. (2019). This scale is chosen such that the 1-loop perturbative predictions are sufficiently accurate at all redshifts considered.

We now move on to describe the code ReACT which produces predictions for equation (3) under some specification of the background Hubble function $H(z)$, the linear, 2nd and 3rd order Poisson equation modifications $\mu_2, \gamma_2$ (Bose & Koyama 2016) as well as the spherical collapse modification $F$ (see for example Lombriser et al. 2014). This parametrisation is explicitly specified, for the theories we consider, in appendix C.

3 THE CODE: ReACT

In this section we give some details about ReACT. The code is written in C++ and is based on the 1-loop perturbation theory code MG-Copter (Carlson et al. 2009; Bose & Koyama 2016). MG-Copter provides a means of numerically calculating the 1-loop matter power spectrum using the algorithm described in Taruya (2016), which is applicable for general theories of gravity and dark energy (Bose & Koyama 2016; Bose et al. 2018). We have optimised this code to compute the 1-loop matter spectrum much faster than the original version presented in Bose & Koyama (2016). The optimisation also corrects the sampling-dependent accuracy described in Bose & Koyama (2016).

We have added two new libraries to MG-Copter. The first, SCOL, handles both the spherical collapse and virial theorem computations outlined in appendix B, which are needed for the halo-model spectra computations. To do this, we make use of the non-linear differential equation solver package, SUNDIALS8. The equations governing spherical collapse can also be edited fairly easily (for example if one wishes to employ ellipsoidal collapse, see Sheth et al. 2001).

The second library, HAL0, contains all the relevant quantities needed to compute $R(k,z)$. In particular, the following key quantities are explicit functions within this library; the halo mass function $n_{\text{vir}}(M_{\text{vir}}, z)$, the virial concentration $c_{\text{vir}}(M_{\text{vir}}, z)$ and the Fourier transform of the halo density profile $a(k,M_{\text{vir}}, z)$. This makes it easy for the user to edit the form of these quantities for both pseudo and fully modified cosmologies. The default forms for these, and the ones used in the proceeding analyses, are the Sheth-Tormann mass function (Sheth & Tormann 1999, 2002), a power law virial concentration (see for example Bullock et al. 2001) and the halo density profile described in Navarro et al. (1997).

Together with the perturbation theory library, SPT, used to calculate equation (6), one can compute the reaction, equation (3), for a given CDM input power spectrum produced by a Boltzmann equation solver such as CAMB (Lewis & Bridle 2002)9 and a specified model of gravity or dark energy.

Figure 1 presents a schematic of the computation with the quantities roughly colour coded according to the library they are part of. Note that the orange boxes indicate functions that need to be specified by the user for the model of gravity under consideration. Currently, the code includes the following presets with respective theory parameters: Hu & Sawicki (2007) $f(R)$ gravity, the braneworld model DGP of Dvali et al. (2000) ($\Omega_{\text{bm}} = 1/(4H_0^2\Lambda^2)$), wCDM ($w_0, w_a$) and ACDM. Note that for $f(R)$ and DGP we assume a CDM background, but for wCDE one should also modify the Hubble function within ReACT. Various evolving dark energy backgrounds have been included within the code. We direct the reader to appendix C for the details.

We provide an easy-to-use Python interface to ReACT, called pyreact. This interface has also been integrated into the CosmoSIS (Zuntz et al. 2015) parameter inference framework.

We note that all components of the reaction (as well as the reaction itself) are computed by ReACT to better than 0.5% accuracy when compared with the computations of Cataneo et al. (2019), for all models and redshifts considered in that work ($f(R)$, DGP and wCDM at $z = 0, 1$).

4 THE ANALYSIS: IMPACT OF REACT

We now proceed with both demonstrating the speed and consistency of ReACT and provide some preliminary modified gravity forecasts. We do this by conducting two sets of parameter inference analyses employing an implementation of ReACT in CosmoSIS. For these analyses we generate mock data consisting of a $C_l^{ij}$ data vector given by Hildebrandt et al. (2017)

\[
C_l^{ij} = \int_0^{\pi} d\chi \frac{g_i(\chi)g_j(\chi)}{\chi^2} P_{\text{NL}}\left(k = \frac{l}{\chi}, z(\chi)\right),
\]

where $P_{\text{NL}}(k,z)$ is the matter power spectrum at redshift $z$ and the co-moving distance, $\chi$ is integrated from 0 to the horizon distance $\chi_H$. The weights are given by

\[
g_i(\chi) = \frac{3}{2\pi^2} \int_{\chi(z')} d\chi' \frac{n_i(z') - \chi(z')}{\chi(z')} \chi(\chi'),
\]

with $n_i(z)$ being the galaxy distribution in the $i$th bin (see equation 10). $P_{\text{NL}}(k,z)$ is generated using equation (1), with $P_{\text{NL}}^{\text{pseudo}}(k,z)$ being generated using HPCODE.

The mock data also consists of a Gaussian covariance matrix (see equation 2.9 of Barreira et al. (2018) for example). For the covariance matrix we assume a stage IV-like survey such as LSST (Tyson 2018; Amendola et al. 2013). Further, we take 3 tomographic bins in the redshift range $0 \lesssim z \lesssim 2$ with bin edges defined by

8 https://computation.llnl.gov/projects/sundials
9 http://camb.info
Figure 1. An overview of the computation of the non-linear power spectrum. The yellow trapezoid (top, centre) indicates the standard input cosmological parameter set in ΛCDM. These are specified to the Boltzmann solver which computes the unmodified linear power spectrum. The light orange trapezoid (pφ) indicates additional parameters that describe modifications to ΛCDM. These must also be specified, either within ReACT or with the other cosmological parameters in a .ini file when using CosmoSIS. Brown boxes (Ppseudo 1h and P1h-loop) indicate computations performed by standard MG-Copter (SPT and SpecialFunctions libraries). The light blue boxes (Modified Spherical Collapse) indicate computations performed by the SCOL library. The pink boxes (σ2p, σ2, Ppseudo 1h, P1h, E, k⋆ and R) indicate computations performed by the HALO library. The red trapezoids (nvir, cvir and ρh) indicate key quantities in the halo model, all found explicitly in HALO. The bright orange trapezoids (µ, γ2, γ3 and F) indicate quantities related to the modification to ΛCDM, found in SpecialFunctions. These quantities are implemented such that they can be easily modified by the user and that, although not explicit in the flowchart, require pφ as input. The black dot connects the P1h box to the k⋆ box. Also note that σ2p is the variance used in the Ppseudo 1h calculation.

Table 1. Cosmological parameter values and priors for the mock data used in all analyses. We note that the derived parameters σ8 = 0.844, Ωm = 0.314 and S8 = 0.863 for this cosmology. We also show the priors and starting values for the modified gravity parameters used in the ΛCDM mock data analyses.

| Parameter | Mock value and flat prior bounds |
|-----------|---------------------------------|
| H0        | [50, 67.3, 80]                   |
| ns        | [0.9, 0.966, 1.05]               |
| Ωc        | [0.15, 0.265, 0.36]              |
| Ωb        | [0.01, 0.049, 0.13]              |
| 10^9A_s   | [1.65, 2.2, 2.55]                |
| Log[f_R0] | [-8, -7, -5]                    |
| Ω_c      | [0, 0.1, 1.5]                    |

[0.00, 0.48, 0.81, 2.00]10, and unless otherwise stated, we use 19 ℓ bins in the range [20, 3000]. The galaxy distribution follows the following relation (Smail et al. 1994; Chang et al. 2013)

\[
n(z) = 2 \exp \left[ -\frac{z}{0.24} \right].
\]

We perform two sets of analyses. The first set applies predictions for the shear spectrum, equation 8, using the non-linear matter power spectrum predicted using equation (1) to mock data generated with the ΛCDM cosmology described in table 1. In this case we have R = 1 and a ΛCDM P1(k; z). To this data we fit predictions within f(R) and DGP separately, with fR0 kept free and then Ωc kept free, each time setting the appropriate parametrisation within ReACT (see appendix C) in each instance. This aims to give a rough forecast of the level of constraining power future surveys will have on these parameters.

10 These bin widths are chosen to keep the number density of objects roughly the same over all bins.
The second type of analyses will use the same covariance matrix as in the ΛCDM mock data, but the data vector will be produced using ReACT + HMCodes with \( f(R) \) as a preset. We choose the fiducial parameter value \( \log[f_{\text{R0}}] = -5 \) (F5). We will fit this data for different scale cuts, the aim being to get an idea of how constraining the non-linear scales are in the case of an \( f(R) \) cosmology. We also fit this data with the pseudo power spectrum (an \( R = 1 \) model) to investigate the impact of omitting the non-linear corrections described by equation (3).

We note that these analyses are primarily meant to demonstrate the code and not meant to illustrate the accuracy of the framework, which in fact has already been studied in Cataneo et al. (2019) using full N-body simulations. We further investigate the accuracy of the reaction approach in appendix D. Secondary is the investigation of what type of constraints on gravity one can expect from a cosmic shear analysis using various scale cuts.

For all analyses we use the emcee (Foreman-Mackey et al. 2013) sampler module in CosmoSIS with 32 walkers. We sample over the standard cosmological parameters \( \{H_0, n_s, \Omega_m, \Omega_b, A_s\} \) as well as the modified gravity parameters \( f_{\text{R0}} \) and \( \Omega_c \) for their respective analyses. \( \sigma_8, \Omega_m \) and \( S_8 = \sigma_8 \sqrt{\Omega_m/0.3} \) distributions are shown as derived parameters. In all analyses we use a minimum of 200,000 samples, and continue to sample until the distributions exhibit convergence. Rather than give hardware specific estimates on the CPU time taken for these analyses, we observe that analyses including the reaction computation are ~ 5 times slower than the same computation in ΛCDM. The bottle-neck computation is the spherical collapse computation which needs to be done multiple times over a reasonable halo mass range, as in modified gravity the collapse density will depend on halo mass. This can be optimised with a careful choice of differential equation solver and root finder. To a lesser extent, the 1-loop perturbation theory computations are also fairly slow. This computation is done numerically as described in Taruya (2016) and Bose & Koyama (2016). Again, this may be optimised with a better choice of differential equation solver and/or tuning of the accuracy demands of the solver and 1-loop integrals.

### 4.1 ΛCDM mock data

In this section we show results for analyses with different scale cuts: \( \ell_{\text{max}} = 3000, \ell_{\text{max}} = 1500 \) and \( \ell_{\text{max}} = 500 \) using 19, 15 and 8 \( \ell \)-bins respectively, where \( \ell_{\text{max}} \) is the maximum multipole included in the cosmic shear analysis. Table 2 shows the upper 68% and 99.7% confidence limits on the marginalised modified gravity parameters for the various analyses discussed in this section. We warn the reader that these conclusions may depend on inaccuracies in the reaction and HMCodes (see appendix D and figure 1 of Cataneo et al. 2019).

Table 2. Maximum multipole used in the analysis and the upper 68(99.7)% confidence bound on theory parameters around the marginalised mean values.

| \( \ell_{\text{max}} \) | \( \log[f_{\text{R0}}] + 1(3)\sigma \) | \( \Omega_{\text{c}} + 1(3)\sigma \) |
|------------------|------------------|------------------|
| 3000             | -7.29 (-5.98)    | 0.06 (0.28)      |
| 1500             | -7.25 (-5.86)    | 0.08 (0.36)      |
| 500              | -6.96 (-5.46)    | 0.42 (1.46)      |

Note that all analyses, including that using the HMCodes but reporting the parameters with \( f_{\text{R0}} \) and \( \Omega_c \), is recovered with high confidence using the \( R = 1 \) model. If only linear to quasi non-linear scales are used then the constraints worsen by an order of 2.

Finally, we have also done an analysis with an \( \log[f_{\text{R0}}] = -6 \) (F6) mock data vector. In this case the modification is much smaller and no biases are incurred on any parameters when using the \( R = 1 \) model. Further, the fiducial value of \( f_{\text{R0}} \) is also recovered safely within 68% confidence using the \( R = 1 \). On the other hand, this choice of modelling again gives no clear detection of a non-zero value of \( f_{\text{R0}} \).
5 SUMMARY

We have presented ReACT, the first computational tool that accurately and reliably models the non-linear matter power spectrum in generic theories beyond ΛCDM employing the halo-model reaction introduced in Cataneo et al. (2019)11. We furthermore provide a CosmoSIS implementation of this code that enables the performance of efficient MCMC parameter estimation analyses on the theory space. The merits of ReACT and the halo-model reaction approach are summarised below:

- Framework to compute the non-linear power spectrum for wide class of theories beyond ΛCDM including scalar tensor theories and evolving dark energy without any fitting parameters.

Another approach to accurately model the non-linear power spectrum in theories beyond ΛCDM was recently suggested in Hu et al. (2018); Ruan et al. (2020), called CHAM. We do not directly compare against CHAM but note that its level of accuracy is similar to ReACT at $k \leq 1h/\text{Mpc}$, yet is far more computationally expensive and so not currently suited for MCMC type analyses.

Figure 2. MCMC results for an $f(R)$ data analysis of a ΛCDM mock data vector within an LSST-like survey, using $\ell_{\text{max}} = 3000, 1500, 500$ in red (filled contours, solid), green (unfilled contours, dashed) and blue (filled contours, dotted) respectively. Modelling of $C_\ell$ uses ReACT + HiPCode (see equation 1). The mock data fiducial cosmological values are marked as dashed lines.

---

11 Another approach to accurately model the non-linear power spectrum in theories beyond ΛCDM was recently suggested in Hu et al. (2018); Ruan et al. (2020), called CHAM. We do not directly compare against CHAM but note that its level of accuracy is similar to ReACT at $k \leq 1h/\text{Mpc}$, yet is far more computationally expensive and so not currently suited for MCMC type analyses.
Figure 3. MCMC results for a DGP data analysis of a ΛCDM mock data vector within an LSST-like survey, using $\ell_{\text{max}} = 3000$, 1500, 500 in red (filled contours, solid), green (unfilled contours, dashed) and blue (filled contours, dotted). Modelling of $C_\ell$ uses $\text{ReACT} + \text{HFCode}$ (see equation 1). The mock data fiducial cosmological values are marked as dashed lines.

- Speed of computation allows for inference analyses in +6D parameter space on reasonable time scales.
- Accuracy of code predictions for $f(R)$ and DGP are competitive with current state-of-the-art models/fitting formulae.
- There is a clear direction for accuracy improvement:
  
  (i) Improving the accuracy of the pseudo ΛCDM power spectrum which is independent of $\text{ReACT}$.
  
  (ii) Improving the halo model ingredients within $\text{ReACT}$. This is easily implemented as all ingredients are stand alone functions within the code (see section 3).

To demonstrate the performance of this tool, we have conducted various MCMC analyses for two test cases: $f(R)$ and DGP gravity. We employed ΛCDM mock data for these tests with a Gaussian covariance matrix based on LSST-like specifications. For these analyses, with an $\ell_{\text{max}} = 1500$, we find a forecasted constraint of $|f_{R0}| \leq 10^{-5.86}$ for Hu-Sawicki $f(R)$ gravity and $\Omega_{rc} \leq 0.36$ for DGP at the 99.7% confidence level.

Comparing our results to a similar analysis performed by Schneider et al. (2020b,a) we find stronger constraints on $f_{R0}$ by almost one order of magnitude. This discrepancy is readily explained by discrepancies in the modelling of $P_{NL}$. In Schneider
et al. (2020b,a), the authors use the fitting function of Winther et al. (2019). This fitting formula demonstrates relevant inaccuracies for values of $f_{R0}$ not used in the fit. For example, for $f_{R0} = 2 \times 10^{-5}$, the fitting function shows inaccuracies up to 5% for $z \leq 2$ and $k \leq 10h$/Mpc.

The reaction approach used here also demonstrates similar inaccuracies. In particular, the $P_{\text{NL}}^\text{pseudo}$ we adopt, which employs the halo model formula of Mead et al. (2015), is not trained for the exotic primordial power spectra used for the pseudo power spectrum, which will be remedied with the development of an emulator (Giblin et al. 2019). As it stands, HMCode is $\sim 5\%$ accurate on scales $k \leq 10h$/Mpc in $\Lambda$CDM and is the dominant source of inaccuracy in the moderately non-linear regime ($0.1 < k < 3h$/Mpc). Above $k \sim 3h$/Mpc, the reaction prescription also becomes inaccurate and can be compounded with HMCode inaccuracies.

The inaccuracies in the modelling of the reaction, $R(k, z)$, arise from its adoption of reinterpreted $\Lambda$CDM fitted halo-model ingredients such as the Sheth-Tormann mass function. These inaccuracies are highlighted in figures 4 and 5 of Catanese et al. (2019), which show that at $k \sim 10h$/Mpc this basic version implementation, can
Table 3. Maximum multipole used in the F5 mock data analysis and the upper and lower 68% confidence bound on selected parameters with the marginalised mean values. The fiducial cosmological values are \( \sigma_8 = 0.844 \) and \( n_s = 0.966 \), with Log\([f(k)R]\) at \(-5\).

| \( \ell_{\text{max}} \) | Log\([f(k)R]\) ± 1\(\sigma\) | \( \sigma_8 \pm 1\(\sigma\) | \( n_s \pm 1\(\sigma\) |
|----------------|-----------------|-----------------|-----------------|
| 3000          | -5.000 ± 0.17   | 0.843 ± 0.008   | 0.967 ± 0.021   |
| 1500          | -4.986 ± 0.39   | 0.842 ± 0.010   | 0.966 ± 0.022   |
| 500           | -4.76 ± 0.45    | 0.835 ± 0.018   | 0.956 ± 0.028   |
| 3000 (R = 1)  | -5.80 ± 0.53    | 0.861 ± 0.011   | 0.932 ± 0.008   |

have inaccuracies as large as 10% for F5 and up to 3% for F6, which are comparable to the inaccuracies of HBCode.

All this being said, we await ray tracing simulations of modified gravity in order to make more robust claims about the accuracy of our forecasts. We direct the reader to appendix D for further discussion on the accuracy of the reaction approach used here and comparisons to the fitting function of Winther et al. (2019).

For surveys such as Euclid or LSST, the current pipeline can only be safely applied up to \( \ell_{\text{max}} \sim 500 \). Importantly, however, the current code is suitable to much higher \( \ell_{\text{max}} \) for current surveys such as KiDS (Kuijken et al. 2015), HSC (Aihara et al. 2018) and DES (Albrecht et al. 2006), which have larger statistical uncertainties. ReACT is therefore readily applicable for parameter estimation analyses employing the currently available data. We discuss further details in appendix D. Note that work to improve the pseudo spectrum has already begun in Giblin et al. (2019) and we expect to have a ‘pseudo-emulator’ ready for stage IV survey lensing analyses.

We also investigate the impact of the reaction in separate sets of \( f(R) \) mock data, created using ReACT + HBCode. We find that if the reaction is omitted from the modelling when fitting to this data, strong degeneracies and parameter biases may be incurred depending on the value of \( f(R) \), in particular between \( n_s \), \( \sigma_8 \) and \( f(R) \). Thus, for consistent and unbiased constraints on cosmological parameters and gravity in the context of stage IV surveys, the reaction will be important. Further, if only scales within the quasi-linear regime are included, i.e. \( \ell_{\text{max}} = 500 \), we find constraints on \( f(R) \) are degraded by over a factor of 2.

Next, we comment on model uncertainties coming from baryonic effects. Based on simulations and observations, these can be as large as 10 – 30% for scales \( 1 \leq k \leq 10h/\text{Mpc} \) (Chisari et al. 2018; Schneider & Teyssier 2015; Semboloni et al. 2011). These are the scales at which the modelling discussed here becomes inaccurate, even though HBCode provides a means to marginalise over this uncertainty. An emulator to address baryonic effects has been studied in Schneider et al. (2020a,b) and a way to incorporate this emulator into this framework will be the goal of future work.

Further worth noting is that an extension of the current framework has also been developed to include massive neutrinos (Cataneo et al. 2020; Wright et al. 2019) and its implementation into ReACT will be the focus of an upcoming work. We also look to extend the current code to galaxy clustering observables, namely the redshift space power spectrum for biased tracers. This can be done by using the ‘hybrid’ approach as outlined in Bose et al. (2019), which makes use of the Gaussian streaming model (Reid & White 2011). Work is also being conducted in upgrading the current implementation to include a general parameterisation of beyond-\( \Lambda \)CDM physics. Namely, we are looking to parameterise the 1-loop calculations in terms of the effective field theory of dark energy (for example Gubitosi et al. 2013) using the reconstruction method described in Kennedy et al. (2017, 2018), and parametrising the spherical collapse using a PPF-formalism (for example Lombresi 2016). This would culminate in a tool that can comprehensively, consistently and accurately probe allowed deviations from \( \Lambda \)CDM at a very wide range of scales and for a very broad range of models.

APPENDIX A: PERTURBATION THEORY BEYOND \( \Lambda \)CDM

For completeness we briefly describe here the perturbative approach to calculate a generalised density field, and hence the power spectrum at 1-loop order, used in section 2. This is given by the expression

\[
P_{1}-\text{loop}(k, a) = F_{1}(k, a)P_{0}(k) + \mathcal{O}_{2}(k, a) + P^{13}(k, a),
\]

where \( a \) is the scale factor, \( P_{0} \) is the (linear) primordial power spectrum and \( F_{1}(k, a) \) denotes the linear growth, which may be scale-dependent depending on the theory of choice. We begin with the density and velocity divergence fields being treated perturbatively

\[
\delta_{NL}(k, a) = \sum_{n=1}^{\infty} \theta_{n}(k, a), \quad \theta_{NL}(k, a) = \sum_{n=1}^{\infty} \theta_{n}(k, a),
\]

where

\[
\delta_{n}(k, a) \sim \int d^{3}k_{1} \ldots d^{3}k_{n} \delta_{D}(k - k_{1}, \ldots, k_{n})
\]

\[
\times F_{1}(k_{1}, \ldots, k_{n}, a) \delta_{0}(k_{1}) \ldots \delta_{0}(k_{n}),
\]

\[
\theta_{n}(k, a) \sim \int d^{3}k_{1} \ldots d^{3}k_{n} \delta_{D}(k - k_{1}, \ldots, k_{n})
\]

\[
\times G_{0}(k_{1}, \ldots, k_{n}, a) \delta_{0}(k_{1}) \ldots \delta_{0}(k_{n}),
\]

with \( k_{1}, \ldots, k_{n} = k_{1} + k_{2} + \ldots + k_{n} \). The 1-loop matter power spectra terms are then given by

\[
P_{22}(k, a) = \int \frac{d^{3}p}{(2\pi)^{3}} F_{2}(p, k - p, a)^{2} P_{0}(p) P_{0}(|k - p|),
\]

\[
P_{13}(k, a) = 2F_{1}(k, a)P_{0}(k) \int \frac{d^{3}p}{(2\pi)^{3}} F_{3}(p, -p, k, a)P_{0}(p).
\]
To determine the kernels $F_i$, we solve the continuity and Euler equations order by order

$$a \delta'(k) + \theta(k) = -\frac{d^3 k_1 k^2_2}{(2\pi)^3} \delta_0(k - k_2) \alpha(k, k_2) \theta(k_2).$$  \hfill (A6)

and

$$a \theta'(k) + \left(\frac{2 + aH'}{H}\right) \theta(k) - \left(\frac{k}{aH}\right)^2 \Phi(k) = -\frac{1}{2} \frac{d^3 k_1 k^2_2}{(2\pi)^3} \delta_0(k - k_2) \beta(k_1, k_2) \theta(k_1) \theta(k_2).$$  \hfill (A7)

where a prime denotes a derivative with respect to the scale factor and Φ is the Newtonian potential. The kernels $\alpha(k, k_2)$ and $\beta(k_1, k_2)$ are the standard mode coupling kernels

$$\alpha(k_1, k_2) = 1 + \frac{k_1 k_2}{|k|^2},$$  \hfill (A8)

and

$$\beta(k_1, k_2) = \frac{(k_1 - k_2^2)|k_1 + k_2|^2}{|k|^2}. $$  \hfill (A9)

Modifications to gravity enter through the Poisson equation

$$-\left(\frac{k}{aH(a)}\right)^2 \Phi(k, a) = \frac{3\Omega_m(a)}{2} \mu(k, a) \theta(k, a) + S(k, a).$$  \hfill (A10)

where $\mu(k, a)$ is the linear modification to GR, while $S(k, a)$ is a source term capturing non-linear modifications, including those responsible for screening effects. The source term is given by

$$S(k, a) = \int \frac{d^3 k_1 d^3 k_2}{(2\pi)^3} \delta_0(k - k_1 - k_2) \gamma_2(k_1, k_2, a) \delta(k_1) \delta(k_2) \nonumber$$

$$+ \int \frac{d^3 k_1 d^3 k_2 d^3 k_3}{(2\pi)^3} \delta_0(k - k_1 - k_2 - k_3) \gamma_3(k_1, k_2, k_3, a) \times \delta(k_1) \delta(k_2) \delta(k_3).$$  \hfill (A11)

The linear modification $\mu(k, a)$ and higher order $\gamma_i$ modifications to general relativity can be derived once we specify a particular theory. We refer the reader to appendix C for the forms of these functions in $f(R)$ and DGP. Furthermore, we note that this framework is very general and can encompass exotic dark energy models too (see Bose et al. 2018).

We can now calculate the $F_i$ kernels numerically by solving equations (A6) and (A7) order by order, as described in Taruya et al. 2018. The higher order kernels are then integrated as in equation (A4) and equation (A5) to calculate the 1-loop terms.

### APPENDIX B: GENERAL SPHERICAL COLLAPSE

In this work we use the Press-Schechter prescription (Press & Schechter 1974). In this approach, we trace the evolution of a spherical top-hat over-density $\delta$ with radius $R_{TH}$ in a homogeneous background spacetime. The mass and momentum conservation equations govern the evolution of this over-density, and give the following second order differential equation for the top-hat radius (e.g. Schmidt et al. 2009a; Pace et al. 2010)

$$\frac{R_{TH}}{R_{TH0}} = \frac{4\pi G}{3} \left[\tilde{\rho}_m + (1 + 3w)\tilde{\rho}_{eff}\right] - \frac{1}{3} \nabla^2 \Phi,$$  \hfill (B1)

$\tilde{\rho}_m$ is the background matter density, $\tilde{\rho}_{eff}$ is the background energy density of an effective dark energy component having equation of state $w$. In this work we assume a $\Lambda$CDM background for DGP and $f(R)$ theories and so in these cases, $\tilde{\rho}_{eff} = \rho_\Lambda$, the energy density of the cosmological constant, with $w = -1$. For these gravity models, we have a modification to the Poisson equation

$$\nabla^2 \Phi = 4\pi G (1 + \mathcal{F}) \tilde{\rho}_m \delta,$$  \hfill (B2)

where $\mathcal{F}$ parametrises the dependency on the theory of gravity with $\mathcal{F} = 0$ for general relativity.

Using equation B1 we can derive certain key quantities used in prescriptions for the halo mass function, virial concentration and halo density profile. These are then used to compute the one-halo term $P_{TH}(k, z)$ that goes into the reaction, $R(k, z)$ (see equation (3)).

One such key quantity is the non-linear over-density, which can be written as a function of top hat radius as

$$\delta = \left(\frac{R_{TH}}{R_{TH0}}\right)^3 (1 + \delta_i) - 1,$$  \hfill (B3)

where a subscript 'i' denotes the initial value of the quantity. Given a scale factor of collapse, $a_{vir}$, we seek the corresponding initial over-density $\delta_i$ that will provide a collapsed object at that time, i.e. $R_{TH}(a_{vir}) = 0$. Once we have this value of $\delta_i$ one can extrapolate to the desired time using linear theory i.e. $\delta_i(a) = D(a)\delta_{i0}/a_i$, where $D(a)$ is the linear growth rate (see equation A3) in $\Lambda$CDM.

As over-densities collapse, they begin to virialise and eventually become stable structures known as halos. To determine the time at which such halos form ($a_{vir}$), we can solve the virial theorem which can include modified gravity or dark energy (see equations A6-A11 of Cataneo et al. (2019) for example). The time of virialisation can be used to get another key quantity, the over-density at the time of virialisation (e.g. Schmidt et al. 2009a)

$$\Delta_{vir} = [1 + (a_{vir})^{-1}] \left(\frac{\rho_{vir}}{\rho_{vir0}}\right)^3.$$  \hfill (B4)

The corresponding mass of this spherical halo is then

$$M_{vir} = \frac{4\pi}{3} R_{vir}^3 \tilde{\rho}_m 0 \Delta_{vir}.$$  \hfill (B5)

where $\tilde{\rho}_m 0$ is the background matter density today and $R_{vir}$ is the comoving radius of this halo.

### APPENDIX C: MODEL PARAMETRISATIONS

Next we give explicit forms for the parameters currently implemented in ReACT. These include a function characterising the modification to spherical collapse, $\mathcal{F}$, and three functions characterising the modification to each order in perturbation theory up to 3rd order, required for the 1-loop power spectrum computation. Additionally, the background expansion needs to be specified. For all modified gravity scenarios considered in this work, we assume a $\Lambda$CDM expansion history

$$\frac{H(a)}{H_0} = \left(\frac{\Omega_m 0}{a^3} + \Omega_\Lambda\right)^{1/2},$$  \hfill (C1)

where $\Omega_m 0$ is the total matter energy density fraction today and $\Omega_\Lambda$ is the cosmological constant energy density fraction. In our case we have $\Omega_\Lambda = 1 - \Omega_m 0$. $H_0$ is the Hubble constant.

We also write here the explicit form of the spherical collapse equation coded up in ReACT

$$y'' + \frac{H'}{H} y' - \left(1 + \frac{H'}{H}\right) y + \frac{H_0^2}{2a^3} \Omega_m 0(1 + \mathcal{F})\delta (\frac{a}{a_i} + y) = 0,$$  \hfill (C2)
where \( y = R_{\text{TH}}/R_0 - a/a_i \) and the prime denotes derivatives \( d/d \ln a \), and \( a_i \) is the initial scale factor.

We have considered two modifications to gravity to test ReACT: Hu-Sawicki \( f(R) \) gravity (Hu & Sawicki 2007) and the normal branch of DGP (Dvali et al. 2000). Note that in the current form, the code requires the specification of the theory parameters for the particular theory under consideration. A future goal is to implement a generalised parametrisation for modified gravity and dark energy.

**C1 DGP gravity**

The DGP model (Dvali et al. 2000) of gravity assumes that we live on a four-dimensional brane embedded in a five-dimensional spacetime bulk. The linear modification to the Poisson equation, \( \mu(k, a) \), is given in the normal branch of DGP by

\[
\mu(k, a) = 1 + \frac{1}{3\beta} \, . \quad \beta(a) = 1 + \frac{H}{H_0} \sqrt{\frac{\Omega_a}{3\beta}} \left( 1 + a\frac{H'}{3H} \right)^3. \tag{C3}
\]

Here we choose to parameterise the additional free parameter of the theory, the scale at which gravity dilutes into the 5th dimension, \( r_c \), in terms of the associated current fractional energy density \( \Omega_{rc} \equiv 1/(4\pi^2 H_0^2) \). Current cosmological constraints limit the crossover distance \( r_c \) to a few times the Hubble length (Lombriser et al. 2009; Raccanelli et al. 2013; Barreira et al. 2016). The higher order coupling kernels are given by (Bose & Koyama 2016)

\[
\gamma_2(k_1, k_2, a) = -\frac{H_0}{H} \left( \frac{24\pi a\beta}{\Omega_{rc}} \right)^{\frac{1}{2}} \left( \frac{\Omega_{m0}}{a^2} \right)^{\frac{1}{2}} (1 - \mu_{1,2}^2), \tag{C4}
\]

\[
\gamma_3(k_1, k_2, k_3, a) = \left( \frac{H_0}{H} \right)^2 \left( \frac{4\pi a\beta}{\Omega_{rc}} \right)^{\frac{1}{2}} \left( \frac{\Omega_{m0}}{a^2} \right)^{\frac{1}{2}} \times (1 - \mu_{1,2}^2)(1 - \mu_{1,3}^2), \tag{C5}
\]

where \( \mu_{ij} = k_i \cdot k_j \) is the cosine of the angle between \( k_i \) and \( k_j \) and \( k_{1...n} = k_1 + ... + k_n \).

Finally, the spherical collapse modification takes the form (Schmidt et al. 2010)

\[
\mathcal{F} = \frac{2}{3\pi\beta(a)} \left( \frac{\Omega_{m0}}{a^3} \right)^{\frac{1}{3}} \tag{C6}
\]

where

\[
s = \left[ \frac{2\Omega_{m0}\delta_0}{9\alpha^3 a^2 \Omega_{rc}} \right]^{\frac{1}{2}}, \tag{C7}
\]

\( \delta \) being the non-linear over-density given in equation (B3).

**C2 Hu-Sawicki \( f(R) \) gravity**

\( f(R) \) gravity is a class of models in which the Einstein-Hilbert action is generalised to include an arbitrary non-linear function of the scalar curvature. Among various examples for the functional form of \( f(R) \), the Hu & Sawicki (2007) model is particularly well studied (Song et al. 2015; Hamann et al. 2015; Lombriser et al. 2013; Hellwing et al. 2013; Zhao 2014; Okada et al. 2013; Li et al. 2012; Lombriser et al. 2012a,b; Schmidt et al. 2009b; Brax et al. 2008; Song et al. 2007; Burrage & Sakstein 2018; Cataneo et al. 2016, 2015) and provides a simple form with which chameleon-type screening is realised. It is given by

\[
f(R) = -m^2 \left[ c_1(R/m^2)^n + c_2(R/m^2)^n + 1 \right]. \tag{C8}
\]

Current cosmological constraints on this parameter lie in the range of \( |f_{R0}| \lesssim \left( 10^{-6} - 10^{-5} \right) \) (see table 1 of Lombriser (2014) for a summary). In this work, we specifically consider the \( n = 1 \) case. Then, the \( f(R) \) form of the Poisson equation (see for example Koyama et al. 2009; Taruya et al. 2014), is characterised by

\[
\mu(k, a) = 1 + \frac{k^2}{3\Pi(k, a)}, \tag{C9}
\]

\[
\gamma_2(k_1, k_2, a) = -\frac{3}{16} \left( \frac{kH_0}{aH} \right)^2 \left( \frac{\Omega_{m0}}{a^3} \right)^2 \frac{\Xi(a)^5}{\left( f_0^2(3\Omega_{m0} - 4)^2 \right)^2} \times \frac{1}{\Pi(k, a)\Pi(k_1, a)\Pi(k_2, a)}, \tag{C10}
\]

and

\[
\gamma_3(k_1, k_2, k_3, a) = \frac{1}{32} \left( \frac{kH_0}{aH} \right)^2 \left( \frac{\Omega_{m0}}{a^3} \right)^3 \frac{\Pi(k, a)\Pi(k_1, a)\Pi(k_2, a)\Pi(k_3, a)}{\left( f_0^2(3\Omega_{m0} - 4) \right)^2} \times \left[ -5 \frac{\Xi(a)}{f_0^2(3\Omega_{m0} - 4)^2} + \frac{9}{2} \frac{\Pi(k_2, a)}{\Pi(k_3, a)} \right] \left( \frac{\Xi(a)^5}{\left( f_0^2(3\Omega_{m0} - 4)^2 \right)^2} \right)^2, \tag{C11}
\]

where the functions \( \Pi \) and \( \Theta \) are given by

\[
\Pi(k, a) = \left( \frac{k}{a} \right)^2 + \frac{\Xi(a)}{f_0^2(3\Omega_{m0} - 4)^2}, \tag{C12}
\]

\[
\Xi(a) = \frac{\Omega_{m0} + 4\alpha^3(1 - \Omega_{m0})}{a^3}, \tag{C13}
\]

with \( f_0 = |f_{R0}|/H_0 \), \( f_{R0} \) is the current amplitude of \( f_R = df(R)/dR \), which can be interpreted as the current amplitude of the scalar field in an equivalent scalar-tensor theory (e.g. present scalaron amplitude).

Finally, the spherical collapse modification takes the form (Lombriser et al. 2014)

\[
\mathcal{F} = \min \left[ O - O^2 + \frac{O^3}{3} \right], \tag{C14}
\]

where

\[
O = \frac{f_0\delta_{b0}(3\Omega_{m0} - 4)^2}{\Omega_{m0}R_{\text{TH}}^2} \times \left[ \tilde{G}(x_{\text{env}}) - \tilde{G}(x_b) \right], \tag{C15}
\]

and

\[
\tilde{G}(x) = \frac{\Omega_{m0}}{(x\alpha)^2} + 4 - 4\Omega_{m0}, \tag{C16}
\]

with

\[
x = \frac{R_{\text{TH}}}{\alpha}, \tag{C17}
\]

\( x_b \) being the quantity solved for the \( f(R) \) halos whereas \( x_{\text{env}} \) is that for the environment, i.e. with \( f_0 = 0 \).

**APPENDIX D: ACCURACY OF REACT**

The halo model reaction approach and ReACT have been shown to be very promising means of modelling the matter power spectrum, with ReACT able to be applied to general beyond-ΛCDM models, requiring no fits, nor simulation measurements. Here we aim to detail
the current code version’s accuracy, that is the reaction combined with a pseudo power spectrum as predicted by HMCode. As a test case, we will consider \( f(R) \) gravity. Means of improving the overall accuracy of ReACT are clear and are discussed briefly in section 5. Such improvements would be applicable to all models of gravity and dark energy and not just \( f(R) \), such as the development of an emulator for the pseudo power spectrum Giblin et al. (2019).

Recently, an accurate fitting formula for the Hu-Sawicki model was developed in Winther et al. (2019), which is also the formula adopted in the cosmic shear mock data analysis of Schneider et al. (2020b), where the authors find constraints of \( \log[f_{R0}] < -5.7 \) at 1σ significance for an LSST-like survey. In this work, using similar survey specifications and \( f_{\text{max}} \), we find constraints that are an order of magnitude more stringent. This is largely related to an excess of power predicted by ReACT + HMCode over the fitting formula for \( \log[f_{R0}] \leq -6 \) (see figure D1). Further, differences in the analyses, such as mock data uncertainties, linear theory and treatment of systematics such as intrinsic alignments will also play a role.

This being said, the ReACT + HMCode pipeline applied in this work and the fitting formula share inaccuracies of a similar order at scales \( k \leq 1h/Mpc \) (∼2%) and \( 1 \leq k \leq 5h/Mpc \) (∼5%). Above \( k \approx 5h/Mpc \), inaccuracies in the reaction become non-negligible and when compounded with the inaccuracies from HMCode make ReACT + HMCode less accurate than the fitting formula. The limitations of the reaction approach used in this work were already noted in Cataneo et al. (2019) (see figure 6 of this reference, for example). One can see the limitations of the fitting formula approach in figure 6 and figure 7 of Winther et al. (2019).

In figure D1 we show the ratio of the auto and cross cosmic shear \( C_{\ell} \) in \( f(R) \) gravity to the same quantity in ΛCDM over all tomographic bins used in the analyses of section 4. We show the predictions as given by ReACT + HMCode and the fitting formula of Winther et al. (2019). We also show the HMCode prediction for the pseudo power spectrum for comparison. The ΛCDM spectrum in all these cases are computed by setting \( f_{R0} = 0 \) in the respective codes.

Finally, overlaid are representative 1σ Gaussian error bands of two different surveys: a future experiment such as LSST (same errors as in section 4) and an ongoing/finished one such as KiDS (Kuijken et al. 2015) for which we assume a sky fraction of \( f_{\text{sky}} = 0.024 \), number density of galaxies per arcminute squared \( n = 3.5\text{arcmin}^{-2} \) per tomographic bin and shape noise parameter \( \sigma_r = 0.28 \). The tomographic binning in both cases is as follows. Bin 1 : \([0.00, 0.48]\),

\begin{equation}
\binom{2}{} : \[0.48, 0.81]\) and \( \bin 3 : \[0.81, 2.00] \). We also show a 5% error band around the fitting formula prediction for F5 (red solid), which represents systematic errors coming from modelling uncertainty. This indicates that the differences between the modelling used here and that of Winther et al. (2019) are consistent to within the systematic uncertainty. This result is also confirmed in Bose et al. (2019) where the authors find the fitting formula and the reaction approach to be consistent within 5% at scales \( k \leq 3h/Mpc \) and for \( z \leq 1 \).

We find that for a KiDS-like survey, both the reaction and fitting formula modelling for \( C_{\ell} \) are acceptable up to \( \text{max} \sim 3000 \) if we want to constrain \( \log[f_{R0}] \) down to the −6-level, which is roughly the limit of this survey given our specifications. Note that this of course assumes statistical errors only and accounting for systematics will significantly degrade this upper bound. For tighter constraints than this, modelling needs to be improved as the uncertainty between these two state-of-the-art approaches becomes comparable to the statistical uncertainty of the measurement.

For an LSST-like survey, the differences between the two approaches becomes far larger than the statistical uncertainty at small scales (large \( f \)). HMCode is not sufficiently accurate for such a survey and so improvement needs to be made here before this methodology can be safely applied to these surveys. Such improvement is already underway (Giblin et al. 2019).

MNRAS 000, 1–14 (2019)
Figure D1. Ratio of cross and auto correlations between 3 tomographic bins in the redshift range of $z \in [0, 2]$ of the cosmic shear $C_{\ell}$ between $f(R)$ gravity and CDM. Predictions for the pseudo spectrum using HMCode are shown as dotted lines, the reaction-corrected pseudo spectrum using ReACT and HMCode are shown as dashed lines and the fitting formula of Winther et al. (2019) are shown as solid lines. Red curves correspond to a value of $\log[f(R_0)] = -5$, green curves correspond to a value of $\log[f(R_0)] = -6$, whereas blue curves correspond to the value $\log[f(R_0)] = -8.0$. The beige 1σ Gaussian error bands represent a KiDS-like survey while the red error bands represent an LSST-like survey. The blue band represents a 5% systematic uncertainty in the modelling. The dashed line predictions took a total of 59 seconds to obtain on a single core of the baobab cluster at the University of Geneva.
