Abstract: Solid oxide fuel cells (SOFCs) are promising and rugged solid-state power sources that can directly and electrochemically convert the chemical energy into electric power. Direct-hydrocarbon SOFCs eliminate the external reformers; thus, the system is significantly simplified and the capital cost is reduced. SOFCs comprise the cathode, electrolyte, and anode, of which the anode is of paramount importance as its catalytic activity and chemical stability are key to direct-hydrocarbon SOFCs. The conventional SOFC anode is composed of a Ni-based metallic phase that conducts electrons, and an oxygen-ion conducting oxide, such as yttria-stabilized zirconia (YSZ), which exhibits an ionic conductivity of $10^{-3} – 10^{-2}$ S cm$^{-1}$ at 700 °C. Although YSZ-based SOFCs are being commercialized, YSZ-Ni anodes are still suffering from carbon deposition (coking) and sulfur poisoning, ensuing performance degradation. Furthermore, the high operating temperatures (>700 °C) also pose challenges to the system compatibility, leading to poor long-term durability. To reduce operating temperatures of SOFCs, intermediate-temperature proton-conducting SOFCs (P-SOFCs) are being developed as alternatives, which give rise to superior power densities, coking and sulfur tolerance, and durability. Due to these advances, there are growing efforts to implement proton-conducting oxides to improve durability of direct-hydrocarbon SOFCs. However, so far, there is no review article that focuses on direct-hydrocarbon P-SOFCs. This concise review aims to first introduce the fundamentals of direct-hydrocarbon P-SOFCs and unique surface properties of proton-conducting oxides, then summarize the most up-to-date achievements as well as current challenges of P-SOFCs. Finally, strategies to overcome those challenges are suggested to advance the development of direct-hydrocarbon SOFCs.

Keywords: proton-conducting oxides; direct-hydrocarbons SOFCs; coking; durability

1. Introduction

Fossil energy sources, including coal, oil, and natural gas, are currently accounting for >80% of the global energy consumption. The rapid growth in fossil fuel extraction, transportation, and consumption is leading to significant anthropogenic climate change and global warming accompanied by the principal CO$_2$ emission [1,2]. Additionally, fossil fuels are not sustainable, and their depletion has been identified as a near-future challenge. Therefore, great efforts have been devoted to ensuring a global economy transition to more efficient utilization of fossil fuels and a low-carbon future [3].

Solid oxide fuel cells (SOFCs) have stimulated great interest in highly efficient energy conversion [4]. As electrochemical energy conversion devices, SOFCs can directly and electrochemically convert the chemical energy stored in fuels into clean electric power without the limitation of the Carnot cycle, which, in turn, leads to higher energy conversion efficiency (~60%) than traditional combustion engines [5]. For example, gas turbines are applied to produce electricity from coal or natural gas using the intermediary steam with lower energy efficiency ranging from 30–40% [6]. Hydrogen is considered as the cleanest fuel, leaving only water as the product, while it is not naturally abundant, and there are many complications in its production, transportation, and storage [7]. Hydrocarbons could offer several attractive advantages over hydrogen, including higher volumetric energy storage density (10.05 kJ/L for hydrogen (LHV) and 36.4 kJ/L for natural gas) and lower...
transportation cost. For example, in the USA, natural gas or propane is usually distributed through railroad, truck, tanker ship, or pipelines into urban areas. Direct-hydrocarbon SOFCs are, therefore, one of the most promising power sources, which eliminates the fuel processor units and could be integrated into the current power grid, drastically enhancing energy conversion efficiency and reducing emissions.

The SOFC anode, which functions as the catalyst for reforming fuel streams and the electrode for charge transfer, is critical for high-performing direct-hydrocarbon SOFCs. The current SOFC anode is typically a composite of ceramic and metal (i.e., cermet) that exhibits mixed ionic and electronic conduction. For instance, the YSZ-Ni cermet is widely used as the anode for oxygen-ion SOFCs (O-SOFCs) because of its excellent catalytic activities and high electronic conductivity [8]. Unfortunately, Ni is vulnerable when exposed to hydrocarbon fuels as it is kinetically favorable for carbon deposition. Additionally, YSZ-Ni anodes are more prone to coking and sulfur poisoning because the relatively acidic surface of YSZ could not contribute to coke mitigation [9–11]. Furthermore, the YSZ-Ni cermet requires an operating temperature of >700 °C, which could thermodynamically favor the coking ascribed to the pyrolysis of hydrocarbons [12]. Since Ni-based anodes are not perfect for working under hydrocarbons, developing Ni-free or oxide-based anodes are emerging approaches to enhancing the durability of direct-hydrocarbon SOFCs [13]. Despite Ni-free anodes delivering good fuel cell performances under hydrocarbon fuels [14], Ni-free anodes are still far away from commercialization and the cell configuration is limited to electrolyte-supported SOFCs. Furthermore, Ni-free anodes need a higher operating temperature (>800 °C) to obtain considerable catalytic activities, and thus the costly balance of plant (BOP) components are required. Hence, few Ni-free anodes demonstrate electro-catalytic activity and electronic conductivity that can compete with the current Ni-based anode. Therefore, robust SOFC anodes, which are catalytically active at intermediate operating temperatures, coking and sulfur-tolerant, as well as chemically stable, are essential for direct-hydrocarbon SOFCs. Proton-conducting oxides have been developed for numerous electrochemical devices because of high proton conductivity at 300–650 °C [15–19]. Due to their relatively basic surface for high water-uptake capability, such oxides are recently applied as anodes for direct-hydrocarbon P-SOFCs. SOFCs with proton-conducting oxides have demonstrated excellent power density and long-term durability (>1000 h), opening a new pathway for developing durable direct-hydrocarbon P-SOFCs [20–22].

Comprehensive aspects of hydrocarbon-fueled SOFCs [7,23–29] and hydrogen-powered P-SOFCs have been summarized by many review papers [21,30,31]. However, there is still a lack of review centering on the hydrocarbon-fueled P-SOFCs [32]. In this review, the fundamentals and recent progress of the P-SOFC development on hydrocarbon fuels are presented. The current challenges and future perspectives of these promising P-SOFCs are highlighted.

2. Proton-Conducting Oxides

The state-of-the-art proton-conducting oxides are ABO₃ perovskites, including five compositional groups: yttrium-doped barium zirconate (BZY), yttrium-doped barium cerate (BCY), yttrium- and cerium-doped barium zirconates (BZCY/BCZY), and yttrium-, ytterbium, and cerium-doped barium zirconates (BCZYYb) [18,31,33,34]. Due to the relatively low activation energy of proton conduction (0.4–0.6 eV), the proton-conducting oxides exhibit practically significant proton conductivity (10⁻³–10⁻² S cm⁻¹) at intermediate operating temperatures (400–600 °C) [31,35].

\[
H_2O + V_{O}^{**} + O_X^\bullet \rightarrow 2OH_{O}^\bullet
\]  

(1)

The protons are produced via hydration [31], as shown in Equation (1), where Kröger-Vink notation is used to describe oxygen vacancy \(V_{O}^{**}\), lattice oxygen \(O_X^\bullet\) and proton. This defect reaction indicates oxygen vacancies are required for the formation of protons \(OH_{O}^\bullet\), thus, oxygen vacancy concentration is normally increased by the acceptor doping to
improve the proton conductivity, i.e., the substitution of the Zr\(^{4+}\) or Ce\(^{4+}\) host with trivalent dopants (e.g., Y\(^{3+}\)/Yb\(^{3+}\)).

In the 1980s, Iwahara et al. first recognized that BCY is a proton conductor [15]. However, it was noted that BCY is chemically unstable in the presence of water and carbon dioxide [31,36]. Their poor chemical stability hinders their practical applications and much attention has been shifted to zirconate-based proton conductors, especially BZY, due to their enhanced chemical stability [16]. However, with the increased concentration of Zr\(^{4+}\), its poor sintering ability tends to be a thorny issue. Additionally, BZY displays high grain boundary resistance, resulting in lower proton conductivity than BCY [31]. The researchers, therefore, developed BCZY by synergizing the benefits of both BZY and BCY, improving conductivity and stability [16]. Liu et al. demonstrated that BaCe\(_{0.7}\)Zr\(_{0.1}\)Y\(_{0.2}\)O\(_3\) possesses improved chemical stability under 2% CO\(_2\) and 15% H\(_2\)O atmosphere and enhanced conductivity (9 \(\times\) 10\(^{-3}\) S cm\(^{-1}\)) at 500 \(^\circ\)C [17]. The same team then pioneered a novel proton conductor, BaCe\(_{0.7}\)Zr\(_{0.1}\)Y\(_{0.1}\)Yb\(_{0.1}\)O\(_3\) [18], leading to benchmarking proton conductivity and stability under hydrocarbons with hydrogen sulfide.

To tackle the issues associated with sintering, a sintering aid (e.g., ZnO) was added to facilitate the densification and lower the sintering temperatures, increasing the feasibility of using proton-conducting oxides for building fuel cells [37]. A variety of other sintering aids, including NiO and CuO, have also been investigated for fabricating proton-conducting oxides [38]. In 2015, Duan and O’Hayre et al. [22] applied the solid-state reactive sintering method to P-SOFCs fabrication and demonstrated P-SOFCs with remarkable performances and durability with both hydrogen and methane as fuels.

3. Unique Surface Properties of Proton-Conducting Oxides

It has been recognized that increasing the basicity of the catalyst surface can suppress coking over heterogeneous catalysts [10]. Tatsuya et al. [39] investigated the catalytic activity and coking tolerance of Ni-YSZ cermet decorated with four alkaline oxides, including MgO, CaO, SrO, and CeO. CaO was identified as the most effective in improving coking tolerance, although it slightly deteriorated the electrochemical activity of the anode. Liu et al. [40] later demonstrated that the modification of the Ni + YSZ anode with nanostructured BaO, which also has a relatively basic surface, could greatly suppress the coke formation. Density functional theory suggests that BaO is capable of absorbing and dissociating water and, thereby, enabling coke mitigation. The water-mediated carbon removal mechanism is illustrated in Figure 1. (1) The basic surface of BaO promotes the dissociation of water into OH\(^*\) and H\(^*\) over the catalyst (* indicates the surface site of catalyst); (2) OH\(^*\) absorbed on BaO will then react with carbon deposited on the Ni and produce CO\(^*\) and H\(^*\). (3) CO\(^*\) and H\(^*\) will subsequently react with the oxygen ions at the triple phase boundary and form CO\(_2\) and H\(_2\)O.

![Figure 1. Proposed mechanism for water-mediated carbon removal on the anode with BaO/Ni interfaces [40].](image-url)
Surface-enhanced Raman Spectrology (SERS) was employed to better understand the coke mitigation mechanisms of Ni-based anodes coated with BaO, BZY, and BCZYYb, respectively [41], revealing that abundant –OH is absorbed on all three materials. These absorbed –OH can readily react with carbon and subsequently clean coke. However, BaO can also easily react with CO₂ and form BaCO₃, which is irreversible, leading to exacerbated SOFC performance degradation. Unlike BaO, BZY and BCZYYb are capable of regenerating –OH groups, and proton-conducting oxides also have basic surfaces, indicating they could be adopted as the materials for direct-hydrocarbons/ethanol SOFCs. Liu et al. integrated BZCY-Ni with SDC as the anode of direct-ethanol SOFCs, aiming to improve its coking tolerance. They demonstrated ethanol-fueled SOFCs with a power density of 750 mW cm⁻² at 750 °C and a stable operation of 170 h. A similar water-mediated carbon removal mechanism was also proposed in this work, suggesting proton-conducting oxides (i.e., BZCY) with high water uptake capacity could accelerate the formation of C–OH intermediates and consequently enhance the carbon removal ability. Furthermore, it has been noted that proton-conducting oxides, such as BCZYYb, can also absorb CO₂ and form –CO₃ groups, which can help to clean the carbon, further improving the coking tolerance [18].

4. The Rationale for Developing Direct-Hydrocarbon P-SOFCs

Although P-SOFCs are a nascent technology, they already show significant promise for highly efficient and durable power generation [19,20,22,32,34,42,43]. Compared to high-temperature oxygen-ion solid oxide cells (O-SOFCs) and low-temperature polymer electrolyte membrane fuel cells (PEMFCs) or alkaline fuel cells, P-SOFCs offer several important benefits:

1. Unlike O-SOFCs (Figure 2b), as illustrated in Figure 2a, P-SOFCs can produce water in the cathode, which will not dilute the fuel stream, potentially improving the performances, enhancing fuel utilization, and reducing system complexity and cost (that is, no external condenser required for condensing water and recycling fuel), as well as enhancing overall energy efficiency [4,44].

2. Intermediate-temperature P-SOFCs (500–600 °C) enable significantly higher efficiency than low temperature (50–100 °C) PEMFCs and can approach that of HT-SOFCs (700–900 °C) [45,46]. Reduced operating temperatures (versus O-SOFCs) enable the relaxing of the stack and balance-of-plant constraints, potentially lowering the cost while also improving the reliability, thermal cycling tolerance, and dynamic response.

3. High hydrocarbon conversion could be achieved in the P-SOFCs because of the continuous removal of hydrogen from the anode which shifts the reaction equilibriums of steam reforming and water gas shift reaction [22].

4. As shown in Figure 3 [20], the composition of P-SOFC anode gas stream lies in the thermodynamic coking boundary of the whole reaction range or just outside it. On the contrary, with increasing the fuel utilization, the composition of anode gas steam in O-SOFC moves away from the coking boundary rapidly. However, the experimental studies of P-SOFCs contradicts the thermodynamic predictions [20,22,34,43], which is due to unique surface properties of proton-conducting oxides. P-SOFCs are therefore coking and sulfur tolerant, and highly active for internal reforming.
5. Notable Achievements on Coking-Tolerant Direct-Hydrocarbon P-SOFCs

Both P-SOFCs and O-SOFCs are capable of directly converting methane and other hydrocarbon fuels (e.g., C$_2$H$_6$ and C$_3$H$_8$) into electricity. However, coking on YSZ-Ni anode, which blocks the active sites at the triple phase boundary (TPB), results in severe degradation. This is the main obstacle to the commercialization of SOFCs. For example, Yang et al. [40] reported that the terminal voltage of O-SOFCs, when fed with dry C$_3$H$_8$, quickly dropped to nearly zero at a current density of 500 mA cm$^{-2}$ within the 30 min operation. There are, therefore, increasing efforts devoted to developing alternative direct-hydrocarbon fuel cells, such as P-SOFCs.

Direct-methane P-SOFCs were firstly validated by Coors in 2003. Although the current densities are too low to be commercially visible at that time, it has been demonstrated that P-SOFC shows the unique coking resistance [47]. Luo et al. [2] proved the feasibility of using propane as the fuel in P-SOFCs, achieving improved fuel cell performances [48]. Duan and O’Hayre et al. [22] employed solid state reactive sintering to fabricate P-SOFCs, tackling the manufacturing challenges arising from the poor sintering ability of proton-conducting oxides. Additionally, they deliberately designed one of the state-of-the-art triple-conducting (oxygen ion, proton, and electron hole) cathodes (BaCe$_{0.4}$Fe$_{0.4}$Zr$_{0.1}$Y$_{0.1}$O$_{3}$), significantly improving the performances of P-SOFCs. Direct-methane P-SOFCs with remarkable performances and a stable operation of 1400 h at 500 °C were demonstrated [22]. In 2017, Liu et al. [49] reported BaCe$_{0.7}$Zr$_{0.1}$Y$_{0.2}$O$_{3-δ}$ electrolyte-supported cells with a peak power density of 348.84 mW cm$^{-2}$ and 496.2 mW cm$^{-2}$ on ethane and hydrogen, respectively at
750 °C. More recently, the long-term durability of fuel-flexible P-SOFCs has been comprehensively investigated. P-SOFCs fueled with 12 different fuel streams, including hydrogen, methane, natural gas, propane, n-butane, i-butane, iso-octane, and others, exhibit a degradation rate of <1.5% per 1000 h for most fuels at 500–600 °C [20]. This entire set of durability measurements have fully validated that direct-hydrocarbon P-SOFCs are exceptionally stable. In addition to power generation, Luo et al. revealed that P-SOFCs can simultaneously generate power and produce chemicals [50]. Both outstanding fuel cell performances and syngas production rate have been achieved. The performances of hydrocarbon fueled P-SOFCs are summarized in Table 1.

Table 1. Performances of P-SOFCs fed with hydrocarbon fuels.

| Year | Anode/Electrolyte/Cathode | Fuel | Peak Power Density (mW cm\(^{-2}\)) | Stability | Reference |
|------|---------------------------|------|-------------------------------------|-----------|-----------|
| 2003 | Ni/BCY/Pt | CH\(_4\) | ~13 at 700 °C | - | [47] |
| 2008 | Pt/BCY/Pt | C\(_3\)H\(_8\) | ~43 at 650 °C | - | [2] |
| 2015 | Ni-BZY20/BCFZY | 28.6% CH\(_4\) + 71.4% H\(_2\)O | 142 at 500 °C | No degredation for 200 h, 0.15 A cm\(^{-2}\) at 500 °C | [22] |
| 2016 | Ni-BCZY/BCZY/PSCFM | C\(_2\)H\(_6\) | 120 at 650 °C | No degredation for 200 h, 0.65 A cm\(^{-2}\) at 750 °C | [49] |
| 2016 | Ni-BCZYYb/BCZY/LSCF | CH\(_4\) (3% H\(_2\)O) | 800 at 650 °C | No degradation for 200 h, 0.50 A cm\(^{-2}\) at 550 °C | [50] |
| 2016 | Ni-BZY/BCY+/NBCo | 50% CH\(_4\) + 50% CO\(_2\) | 560 at 700 °C | No degradation for 36 h, 1.0 A cm\(^{-2}\) at 700 °C | [42] |
| 2017 | BCZYYb/BZCY-LSGM/BZCY-LSCF | Humidified 60% CH\(_4\) + 40% CO\(_2\) | 210 at 500 °C, 320 at 550 °C, 560 at 600 °C | No degradation for 80 h, 1.5 A cm\(^{-2}\) at 650 °C | [51] |
| 2018 | Ni-BZY/BZY/BCFZY | Natural gas with 19.5 p.p.m. H\(_2\)S impurity | 372 at 600 °C | ~10% degradation for 1000 h, 0.25 A cm\(^{-2}\) at 500 °C | [20] |
| 2018 | Ni-BZY/BZY/LSCF-PNM | 33% CH\(_4\) + 33% H\(_2\)O + 33% N\(_2\) | 55 at 550 °C, 96 at 600 °C, 132 at 650 °C | No degradation for 20 h, 0.6 V at 550 °C | [52] |

To improve the durability of direct-hydrocarbon O-SOFCs, proton-conducting oxides have also been used for decorating the anode of O-SOFCs [53,54]. Proton-conducting nanoparticles are infiltrated into the anode and distributed over the Ni particles. These proton-conducting nanoparticles with basic surface can absorb and dissociate water, as abovementioned, which subsequently react with deposited carbon or sulfur; thus, this approach alleviates coking and sulfur poisoning. For example, the peak power density of direct-methane SOFCs at 650 °C was improved from 0.62 W cm\(^{-2}\) to 1.27 W cm\(^{-2}\) after decorating the Ni-GDC anode with BCY particles, indicative of the bifunctionality of proton-conducting oxides [53].

6. Conclusions and Perspectives

Due to the unique surface properties of proton-conducting oxides, P-SOFCs are one of the keys enabling technologies for directly and efficiently converting hydrocarbons into electricity. Although significant progress has been made in developing advanced proton-conducting oxides, there is a lack of material with both high proton conductivity and great chemical stability under more realistic working conditions, such as fuel streams...
containing high-concentration impurities (CO₂, NOₓ, and H₂S). Additional efforts are, therefore, urgently required for the development of proton-conducting oxides with higher proton conductivity, improved chemical stability, and enhanced sinterability, as well as P-SOFCs with novel structures, higher performances, and longer lifetime.

**Author Contributions:** F.L. led the manuscript writing. C.D. and F.L. developed the intellectual concept of this manuscript. C.D. led the manuscript refinement. All authors have read and agreed to the published version of the manuscript.

**Funding:** This research was funded by Kansas State University tenure track faculty research funding.
