We discuss the heavy quark spin structure of the recently observed ‘twin’ resonances $Z_b(10610)$ and $Z_b(10650)$ assuming that these are mostly of a ‘molecular’ type, i.e. that their internal dynamics is dominated by the coupling to meson pairs $B^*\bar{B} - BB^*$ and $B^*\bar{B}^*$. We find that the state of the $b\bar{b}$ pair within the $Z_b(10610)$ and $Z_b(10650)$ resonances is a mixture of a spin-triplet and a spin-singlet of equal amplitude and with the phase orthogonal between the two resonances. Such a structure gives rise to specific relations between observable amplitudes that are in agreement with the data obtained recently by Belle. We also briefly discuss possible properties of the isotopically singlet counterparts of the newly found resonances, and also of their $C (G)$ parity opposites that likely exist in the same mass range near the open $B$ flavor threshold.

PACS numbers:

Very recently the isotriplet resonances $Z_b(10610)$ and $Z_b(10650)$ were discovered in the processes $\Upsilon(5S) \to \pi\pi h_b(kP)$, and $\Upsilon(5S) \to \pi\pi T(nS)$, Ref. [1]. Here and bellow $n = 1, 2, 3$ and $k = 1, 2$. For simplicity we refer to $Z_b(10610)$ and $Z_b(10650)$ as $Z_b$ and $Z_b'$. Data analysis has shown that these processes go mainly as cascades, e.g., $\Upsilon(5S) \to Z_b\pi \to h_b\pi\pi$. The new bottomonium-type resonances apparently have quantum numbers $I^G(J^P) = 1^+(1^+)$, so that their electrically neutral isotopic states with $I_3^b = 0$ should have $J^{PC} = 1^–$. It turns out that the process with $T(nS)$ in the final state has almost the same probability as those with $h_b$. At first glance this fact looks quite astonishing. Assuming that $b$ and $\bar{b}$ quarks are in a triplet spin state in $\Upsilon(5S)$ and $T(nS)$, and they are in a singlet spin state in $h_b$, one may expect that a process with spin flip should be suppressed in comparison with that without spin flip because of the large mass of the $b$ quark. In this Letter we suggest an explanation of the puzzle. First of all we note that the masses of the newly found states $Z_b$ and $Z_b'$ are close to the respective thresholds of the open $B$ flavor channels $B^*\bar{B}$ and $B^*\bar{B}^*$. Therefore it is natural to suggest that the new resonances have a ‘molecular’ type structure of $B(B^*)$ meson pairs. Namely, the states with the quantum numbers of $Z_b$ and $Z_b'$ can be realized as $S$-wave $B^*\bar{B}$ and $B^*\bar{B}^*$ meson pairs, respectively. A possible ‘molecular’ type structure in the charmonium family was initially discussed in Ref. [2].

The mass differences between the charged and neutral $B(B^*)$ mesons are negligible so that, unlike at the charm threshold, the isotopic symmetry should be well applicable to bottomonium-like multiquark states. Therefor, we suggest that at long distances, $r \gg \Lambda_{QCD}^{-1}$, the wave functions of the $Z_b$ and $Z_b'$ resonances are that of an $S$-wave meson pair in the $I^G(J^P) = 1^+(1^+)$ state, namely, $B^*\bar{B} - BB^*$ for the $Z_b$ and $B^*\bar{B}^*$ for the $Z_b'$. At shorter distances, $r \sim \Lambda_{QCD}^{-1}$, the mesons overlap and form a system containing the heavy quark pair and a light component of quarks and gluons with the quantum numbers of an isotopic triplet.

In the limit $m_b >> \Lambda_{QCD}$, the spin degrees of freedom of $b$ quark in the wave functions $\Psi$ of $B(B^*)$ mesons can be separated from other degrees of freedom. Thus we treat a hyperfine interaction in $B$-meson as a perturbation. As a result, the wave function $\Psi$ can be written as a direct product $\tilde{\psi}_q \otimes \chi_b$, where spinor $\chi_b$ describes the spin state of $b$-quark and $\psi_q$ describes the wave function of the bound light antiquark $\bar{q}$ and spinless $b$-quark. The total angular momentum $j$ corresponding to the wave function $\psi$ is fixed in the ground state $B(B^*)$: $j = 1/2$, and the rules of constructing the wave function $\Psi$ are the same as in the nonrelativistic quark model. The precision of this picture is determined by the ratio $\Lambda_{QCD}/m_b = O(0.1)$ and the expected corrections should be at the level of about 10%.

For $B$ meson we have $\Psi_B = \tilde{\psi}_q\chi_b$, and for $B^*$ meson we have $\Psi_{B^*} = \tilde{\psi}_q\bar{\sigma}\chi_b$, where $\sigma$ are the Pauli matrices. Then the $S$-state of the heavy meson pairs with the appropriate quantum numbers $I^G(J^P) = 1^+(1^+)$ is $B^*\bar{B}^*$:

$$
\begin{align*}
&i \epsilon_{ijk} (\bar{\chi}_b\sigma^i\psi_q)(\tilde{\psi}_q\sigma^j\chi_b) \\
&= (\bar{\chi}_b\chi_b)(\tilde{\psi}_q\sigma^i\psi_q) - (\bar{\chi}_b\sigma^j\chi_b)(\tilde{\psi}_q\psi_q) \\
&\sim 0_{bb}^\pi \otimes 1_{QQ}^\pi - 1_{bb}^\pi \otimes 0_{QQ}^\pi,
\end{align*}
$$

for $B^*\bar{B}^*$. and

$$
\begin{align*}
(\bar{\chi}_b\sigma^i\psi_q)(\tilde{\psi}_q\chi_b) + (\bar{\chi}_b\chi_b)(\tilde{\psi}_q\sigma^i\psi_q) \\
= -(\bar{\chi}_b\chi_b)(\tilde{\psi}_q\sigma^i\psi_q) - (\bar{\chi}_b\sigma^i\chi_b)(\tilde{\psi}_q\psi_q) \\
\sim 0_{bb}^\pi \otimes 1_{QQ}^\pi + 1_{bb}^\pi \otimes 0_{QQ}^\pi,
\end{align*}
$$

for $B^*\bar{B}$. Here we used the Fierz transforms, $0^-$ and $1^-$ stand for para- and ortho- states with the negative parity. Clearly the relations [1] and [2] refer only to the spin variables of the quarks. These relations describe the perfect mixtures of the two possible states corresponding

---

*arXiv:1105.4473v2 [hep-ph] 24 May 2011*
to the para- and ortho- spin states of the $b\bar{b}$ pair. We thus conclude that, if the $Z'_b$ and $Z_b$ peaks are determined by a molecular dynamics of the meson pairs, their heavy quark spin structure should be the same as of the pairs, i.e.,

$$|Z'_b\rangle = \frac{1}{\sqrt{2}} \left( 0_{b\bar{b}} \otimes 1_{Qq}^- - 1_{b\bar{b}} \otimes 0_{Qq}^- \right),$$

$$|Z_b\rangle = \frac{1}{\sqrt{2}} \left( 0_{b\bar{b}} \otimes 1_{Qq}^- + 1_{b\bar{b}} \otimes 0_{Qq}^- \right).$$

(3)

Since the masses of $Z_b$ and $Z'_b$ are very close to sum of the $B$ and $B^*$ masses and $B^*$ and $B$ masses, respectively, the mixture of states in Eq. (3) is small. In this picture the mass splitting between the peaks should be equal to that between the $B$ and $B^*$ mesons: $M(Z'_b) - M(Z_b) = M(B^*) - M(B) \approx 46$ MeV with an expected correction of order $\Lambda_{QCD}/m_b = O(1 \div 5)$ MeV. The spin structure described by Eq. (3) also leads to an important and experimentally testable conclusion that the resonances $Z_b$ and $Z'_b$ should have the same width. Indeed, in the large $m_b$ limit all the ortho- and para- states of the $b\bar{b}$ pair are degenerate, so that the antisymmetric and the symmetric superposition of the spin states in Eq. (3) decay into degenerate (orthogonal) states with lower mass, so that the total decay rates of the discussed resonances should be almost equal: $\Gamma(Z_b) = \Gamma(Z'_b)$. In particular, this also implies that in our approximation the decays of the type $Z'_b \to B^* B$ are forbidden by the heavy quark spin symmetry, in spite of being perfectly allowed by the overall quantum numbers and the kinematics. In other words, the heavy quark spin wave function in the $Z'_b$ is orthogonal to that in the $Z_b$ state.

The maximal ortho-para mixing of the heavy quarks in the $Z_b$ and $Z'_b$ resonances described by Eq. (3) immediately implies that these resonances have coupling of comparable strength to channels with states of ortho- and para-bottomonium. Furthermore, for each specific channel the absolute value of the coupling is the same for $Z_b$ and $Z'_b$. However the relative phase of the coupling of these resonances to the ortho- bottomonium is opposite to that for the para-bottomonium. In particular the coupling of these resonances to the channels $\Upsilon(nS)\pi \pi$ and $h_b(kP)\pi \pi$ can readily be found (up to an overall normalization) as

$$E_\pi \vec{\Upsilon} \cdot (\vec{Z}_b - \vec{Z}'_b), \quad (\vec{p}_\pi \times \vec{h}_b) \cdot (\vec{Z}_b + \vec{Z}'_b),$$

(4)

with $\vec{Z}'_b$, $\vec{\Upsilon}$ and $\vec{h}_b$ standing for the polarization amplitude of the corresponding spin one state, and $E_\pi$ and $\vec{p}_\pi$ being the pion energy and momentum. The amplitudes described by Eq. (4) can be directly applied to the resonance part of the amplitudes of the observed transitions $\Upsilon(5S) \to \Upsilon(nS)\pi^+\pi^-$ and $\Upsilon(5S) \to h_b(kP)\pi^+\pi^-$. We have

$$A(\Upsilon(5S) \to \Upsilon(nS)\pi^+\pi^-) = A^{nr}_{\Upsilon} + C_\Upsilon (\vec{\Upsilon}_5 \cdot \vec{\Upsilon})$$

$$\times E_\pi E_- \left( \frac{1}{E - E_+ + \frac{i}{2} \Gamma} + \frac{1}{E' - E_+ + \frac{i}{2} \Gamma} \right)$$

$$+ \frac{1}{E - E_- + \frac{i}{2} \Gamma} + \frac{1}{E' - E_- + \frac{i}{2} \Gamma},$$

(5)

and

$$A(\Upsilon(5S) \to h_b(kP)\pi^+\pi^-) = A^{nr}_{h_b} + C_{h_b}$$

$$\times \left\{ \vec{\Upsilon}_5 \cdot (\vec{p}_\pi \times \vec{h}_b) \right\} E_+$$

$$\times \left( \frac{1}{E - E_+ + \frac{i}{2} \Gamma} - \frac{1}{E' - E_+ + \frac{i}{2} \Gamma} \right)$$

$$+ \left[ \vec{\Upsilon}_5 \cdot (\vec{p}_\pi \times \vec{h}_b) \right] E_-$$

$$\times \left( \frac{1}{E - E_- + \frac{i}{2} \Gamma} - \frac{1}{E' - E_- + \frac{i}{2} \Gamma} \right),$$

(6)

where $E_+$ and $\vec{p}_\pi$ ($E_-$ and $\vec{p}_\pi$) stand for the energy and momentum of the positive (negative) pion, the parameters $E$ and $\Gamma$ ($E'$ and $\Gamma'$) are those of the $Z_b$ ($Z'_b$) resonance with $E = M[\Upsilon(5S)] - M[Z_b]$ and $E' = M[\Upsilon(5S)] - M[Z'_b]$, the vector $\vec{\Upsilon}_5$ is the polarization amplitude of the initial $\Upsilon(5S)$ resonance and $\vec{\Upsilon}$ and $\vec{h}_b$ are the same for respectively the final $\Upsilon(nS)$ and $h_b(kP)$ resonances. Furthermore, the coefficients $C_\Upsilon$ and $C_{h_b}$ are constants, and, finally, $A^{nr}_{\Upsilon}$ and $A^{nr}_{h_b}$ are the corresponding nonresonant amplitudes. The latter amplitudes generally depend on the polarizations and the kinematical variables $\vec{\Upsilon}$ and $\vec{h}_b$ and can be studied in much the same way as for other similar two-pion transitions between heavy quarkonium states. It can be stated however that the nonresonant amplitude $A^{nr}_{\Upsilon}$ should be heavily suppressed due to the heavy quark spin symmetry and an absence of enhancing factors. In Eqs. (5) and (6) we take into account two isotopic resonant branches, through the $Z'_b$ ($Z'_{b}^\uparrow$) and through $Z_b$ ($Z_b^\downarrow$).

Clearly, the equations (5) and (6) describe two different patterns of the interference between the $Z_b$ and $Z'_b$ resonances in the two considered transitions. In the process $\Upsilon(5S) \to \Upsilon(nS)\pi^+\pi^-$, the interference is destructive when the energy of one of the pions lies between the positions of the resonances, $E'$ and $E$, and the interference is constructive when both energies lie outside of the ‘twin’ resonance band on the Dalitz plot. In the transition $\Upsilon(5S) \to h_b(kP)\pi^+\pi^-$, the pattern is exactly the opposite: the interference is constructive inside the resonance band and is destructive outside the band. In fact, the probability of the latter transition outside the ‘twin’ resonance band on the Dalitz plot should be very small due to the mentioned suppression of the nonreso-
nant amplitude $A_{bb}^\gamma$. Such picture is fully supported by the experimental results Ref. [1].

Based on the considerations presented here, one can expect existence of hadronic transitions from the $Z_b$ and $Z_b'$ resonances to other ortho- and para-bottomonium states. In particular, the transitions $Z_b \to \eta_b \rho$ are of an S-wave type and a significant rate is possible for this process. Following the same consideration as presented above, the resonance amplitudes of the cascade $\Upsilon(5S) \to \eta_b \rho$ should have opposite sign between the $Z_b$ and $Z_b'$ Breit-Wigner factors. The processes of the type $Z_b(Z_b') \to \chi_b(1P) \pi \pi$ are also kinematically possible, but could be suppressed because two pions have to be in the $I^G = 1^+$ state and the $\rho$ peak is beyond the kinematical region. The finding of the $Z_b$ and $Z_b'$ resonances may call for revisiting the analyses of the previously known processes, such as the transitions $\Upsilon(3S, 4S) \to \Upsilon(1S, 2S) \pi \pi$ as well as the decay $\Upsilon(3S) \to h_b(1P) \pi \pi$ for which a significant upper bound has become available recently [2]. A contribution of an isovector bottomonium-like resonance in the decay $\Upsilon(3S) \to \Upsilon(1S) \pi \pi$ was in fact discussed some time ago [3, 4].

The existence or non-existence of ‘molecular’ bottomonium-like resonances depends on details of a yet unknown dynamics. However, the very existence of the $Z_b$ and $Z_b'$ resonances necessarily implies that additional isovector peaks also exist. Indeed, the resonance properties are determined by the interaction of the quasiparticles, which are the bound states of light quarks or quasiquarks, as well as the decay $\Upsilon(3S) \to h_b(1P) \pi \pi$ for which a significant upper bound has become available recently [2]. A contribution of an isovector bottomonium-like resonance in the decay $\Upsilon(3S) \to \Upsilon(1S) \pi \pi$ was in fact discussed some time ago [3, 4].

The existence or non-existence of ‘molecular’ bottomonium-like resonances depends on details of a yet unknown dynamics. \[
\begin{align*}
(B^*\bar{B}^*)_{1^{-(0^+)}} &\sim \frac{\langle \bar{\chi}_b(\sigma) \psi_q \rangle (\bar{\psi}_Q(\sigma) \chi_b)}{\sqrt{3}} \\
&= \frac{\sqrt{3}}{2} \langle \bar{\chi}_b \chi_b \rangle (\bar{\psi}_Q \psi_q) - \frac{1}{2} \langle \bar{\chi}_b(\sigma) \chi_b \rangle (\bar{\psi}_Q(\sigma) \psi_q) \\
&\sim \frac{\sqrt{3}}{2} 1_{bb}^\gamma \otimes 0_{Qq}^\gamma - \frac{1}{2} 1_{bb}^\gamma \otimes 1_{Qq}^\gamma.
\end{align*}
\]

and

\[
\begin{align*}
(B\bar{B})_{1^{-(0^+)}} &\sim \langle \bar{\chi}_b(\psi_q) (\bar{\psi}_Q \chi_b) \rangle \\
&= \frac{1}{2} (\bar{\chi}_b(\chi_b) (\bar{\psi}_Q \psi_q) + \sqrt{3} (\bar{\chi}_b(\sigma) \psi_q) (\bar{\psi}_Q(\sigma) \chi_b)) \\
&\sim \frac{1}{2} 0_{bb}^\gamma \otimes 0_{Qq}^\gamma + \sqrt{3} 1_{bb}^\gamma \otimes 1_{Qq}^\gamma.
\end{align*}
\]

Thus, the mixing angle between para- and ortho-bottomium states of the $bb$ pair in this case is $\pi/6$ which can be readily checked experimentally. Clearly, such resonances form another ‘twin’ pair and couple to both ortho- and para-bottomonium and can thus decay to e.g. $\Upsilon \rho$ as well as to $\eta_b \pi$.

Additionally, if a threshold singularity $1^-$ state contributes to the $Z_b(Z_b')$ resonances, its combination with $1^m_{bb}$ state of the heavy quark pair should also produce an $I^G(J^P) = 1^-(0^+)$ state at the $B^*\bar{B}$ threshold (an isovector bottomonium analog of X(3872) Ref. [5]), and isospin triplet at the $B^*\bar{B}^*$ threshold with spin 2: $I^G(J^P) = 1^-(2^+)$. These latter states couple to ortho-bottomonium, e.g., to the channel $\Upsilon \rho$. Due to the negative $G$ parity all these expected resonances are not accessible in single pion transitions from $\Upsilon(5S)$, but their production can be sought for at a somewhat higher energy above the $B$ flavor threshold. One can also notice that the isotriplet states cannot mix with pure bottomonium states, so that they are unlikely to be produced at Tevatron and/or LHC at a detectable rate.

At this point the ‘molecular’ interaction in the isoscalar channel is not known. However, based on the existence of the $X(3872)$ state in the charmonium family, one may expect an existence of $I = 0$ counterparts of the isos triplet $Z_b$ and $Z_b'$ in the same mass region near the $B^*\bar{B}$ and $B^*\bar{B}^*$ thresholds. Such states, $Y_b$ and $Y_b'$ have the quantum numbers $JPC = 1^{--}$ and can mix with $1^{+}P_l$ states of bottomonium, $h_b(kP)$. Such mixing can generally shift the completely mixed ortho-para-heavy quark spin structure in the $Y_b(Y_b')$ resonances, and it would be interesting if this behavior could be studied experimentally. For the reasons of isospin these resonances are not accessible from the $\Upsilon(5S)$ by single pion transitions, but could be studied in the future at higher initial energies in $e^+e^-$ annihilation. Moreover, the likely presence of the bottomonium $1^P_l$ ‘core’ in the $Y_b(Y_b')$ states makes it possible that, unlike the $Z_b(Z_b')$, these states can be produced in hard processes such as the high-energy $pp$ or $pp$ collisions at the Tevatron and LHC, similarly to the production of $X(3872)$ at the Tevatron [11]. The discussed bottomonium-like resonances can be identified, e.g., by their decay into $\Upsilon(2S) \eta$, or $\Upsilon(1S) \eta$, or $\Upsilon(1S) \eta'$ which all are $S$-wave processes and which one would not expect to be suppressed. Other possibly identifiable in a collider setting decay channels of $Y_b(Y_b')$ are $\Upsilon(1S) \pi \pi$ and $\Upsilon(1S) K K$, including those through the $f_0(980)$ resonance: $Y_b(Y_b') \to \Upsilon(1S) f_0(980)$, although an expecta-
the significance of an admixture in these resonances of
and without hidden strangeness could also shed light on
subtle due to the required orbital momentum of the light
mesons. A comparison of the decay rates to states with
and without hidden strangeness could also shed light on
the significance of an admixture in these resonances of
the states of the type $b\bar{b}s\bar{s}$. The $C$-even states $X_0$ of
the same type can mix with the $3P_1$ bottomonium and
can similarly be produced in hard collisions. These reso-
crances can be sought for at the colliders by their decay,
e.g., into $\Upsilon(1S)\omega$.

In summary, we argue that, if the newly found $Z_b$ and
$Z'_b$ isovector resonances are states of a ‘molecular’ type in
respectively the channels $B^*\bar{B} - BB^*$ and $B^*\bar{B}$ with
the quantum numbers $I^G(J^P) = 1^+(1^+)$, each of them has
to contain (almost) complete mixture of spin-triple and
spin-singlet states of the heavy $b\bar{b}$ pair. The heavy quark
spin wave functions in the two resonances have to be or-
thogonal to each other, as described by Eq.(3). In our
approach using a separation of the $b$ quark spin degrees of
freedom in the wave function of $B$ mesons, based on the
large value of the $b$ quark mass $m_b$, the mass splitting
between $Z'_b$ and $Z_b$ should be the same as between $B^*$ and
$B$ mesons: $M(Z'_b) - M(Z_b) = M(B^*) - M(B) \approx 46$ MeV,
and their total decay widths should be equal to one an-
other: $\Gamma(Z'_b) = \Gamma(Z_b)$. Any deviations from these rela-
tions are due to the finite mass of $b$ quark and should be
small. In particular, a kinematically allowed process
$Z'_b \to B^*\bar{B}$ should be strongly suppressed. Furthermore,
the resonances $Z_b$ and $Z'_b$ should have equal coupling to
specific decay channels with the states of bottomo-
nium. The relative sign between the couplings of $Z_b$
and $Z'_b$ to such channels depends on the spin state of the
bottomonium, this relative sign of the coupling to ortho-
states is opposite to that in the coupling to the para-
states. Such behavior leads to a specific inter-
ferece pattern in the contribution of the discussed reso-
nances to the observed processes $\Upsilon(5S) \to \Upsilon(nS)\pi^+\pi^-$
and $\Upsilon(5S) \to b\bar{b}(kP)\pi^+\pi^-$. Finally, we point out
that a similar behavior can be tested in the yet unobserved,
but expected, processes $\Upsilon(5S) \to \eta_b\rho\pi$ and $\Upsilon(5S) \to \chi_b(1P)\pi\pi\pi$. The coupling of the bottomonium states
to the $Z_b$ and $Z'_b$ resonances can also affect the rates
and the spectra in hadronic transitions in bottomonium,
such as $\Upsilon(3S) \to \Upsilon(1S)\pi\pi$ and/or $\Upsilon(3S) \to h_b(1P)\pi\pi$.
We also suggest that isospin-singlet resonances $Y_0$ and
$Y'_0$ with the quantum numbers $J^{PC} = 1^{+-}$ of a simi-
lar ‘molecular’ structure can mix with the $1^P_1$ states of
bottomonium and can thus be produced in ‘hard’ col-
lusions at the Tevatron and LHC. These states can be
sought for in the high-energy data by their decay chan-
els $\Upsilon(2S,1S)\eta$, $\Upsilon(1S)\eta'$, or $\Upsilon(1S)\pi\pi$ (or $K\bar{K}$),
and a possible isoscalar resonance $X_{50}$ with $J^{PC} = 1^{++}$
can be sought for by its decay into $\Upsilon(1S)\omega$.
