A novel ammonia-oxidizing archaeon from wastewater treatment plant: Its enrichment, physiological and genomic characteristics

Yuyang Li, Kun Ding, Xianghua Wen, Bing Zhang, Bo Shen & Yunfeng Yang

Ammonia-oxidizing archaea (AOA) are recently found to participate in the ammonia removal processes in wastewater treatment plants (WWTPs), similar to their bacterial counterparts. However, due to lack of cultivated AOA strains from WWTPs, their functions and contributions in these systems remain unclear. Here we report a novel AOA strain SAT1 enriched from activated sludge, with its physiological and genomic characteristics investigated. The maximal 16S rRNA gene similarity between SAT1 and other reported AOA strain is 96% (with "Ca. Nitrosotenuis chungbukensis"), and it is affiliated with Wastewater Cluster B (WWC-B) based on amoA gene phylogeny, a cluster within group I.1a and specific for activated sludge. Our strain is autotrophic, mesophilic (25 °C–33 °C) and neutrophilic (pH 5.0–7.0). Its genome size is 1.62 Mb, with a large fragment inversion (accounted for 68% genomic size) inside. The strain could not utilize urea due to truncation of the urea transporter gene. The lack of the pathways to synthesize usual compatible solutes makes it intolerant to high salinity (>0.03%), but could adapt to low salinity (0.005%) environments. This adaptation, together with possibly enhanced cell-biofilm attachment ability, makes it suitable for WWTPs environment. We propose the name "Candidatus Nitrosotenuis cloacae" for the strain SAT1.

Nitrification is a significant biological process for nitrogen removal in wastewater treatment plants (WWTPs). Ammonia oxidation, the first and rate-limiting step of nitrification, is critical for wastewater treatment1. For a long time, it has been believed that this step is solely mediated by ammonia-oxidizing bacteria (AOB), which are affiliated with Betaproteobacteria and Gammaproteobacteria. In the last decade, the discovery and cultivation of ammonia-oxidizing archaea (AOA) in various environments has extended the boundary of ammonia-oxidizers to the domain Archaea. The most important characteristic of AOA is their possession of archaeal amoA gene, which codes for the α-subunit of ammonia monooxygenase, the key enzyme responsible for ammonia oxidation. Using amoA as gene marker, recent investigations revealed that AOA occurred with great abundances in sites such as marine environment and acidic soils.

In WWTPs, Park et al. was the first to report detection of AOA in five plants with low dissolved oxygen (DO) level and long retention time, which suggested potential application of AOA to oxidize ammonia with less DO and consequently low energy consumption. Since then, the presence of AOA has been confirmed in a number of WWTPs worldwide, and the abundances of AOA even outnumbered that of AOB in some of those plants. However, AOA was not widespread in WWTPs as AOB, as Mussmann's study showed that AOA was only detected in 4 out of total 52 plants. A list of operational and environmental parameters had been proposed as influential factors for occurrence and distribution of AOA in WWTPs, including ammonia, dissolved oxygen, salinity and retention time, but their conclusions were often conflict with each other and there has not been a consent point of view. Current studies on AOA in WWTPs have mainly focused on AOA occurrence, abundance and diversity by using culture-independent methods such as quantitative PCR and high-throughput sequencing.
sequencing, combined with statistics tools like correlation analysis, which might lead to large bias due to the limitation of detection and complexity of WWTPs environment\textsuperscript{4,14}. To know AOA precisely, which is the prerequisite of its application, cultivation of AOA from WWTPs is necessary. By focusing on a single strain, one could investigate its physiological characteristics through more accurate experiments.

To date, a number of AOA has been enriched or isolated from various environments, including marine environment\textsuperscript{4,15}, hot spring\textsuperscript{16,17}, neutral soil\textsuperscript{18,19}, acidic soil\textsuperscript{20} and freshwater\textsuperscript{21}, with their whole genome sequence nearly all obtained\textsuperscript{22}. However, no AOA enriched from WWTPs has been reported. In this study, we successfully enriched a novel ammonia-oxidizing archaeon strain SAT1 from a full-scale municipal WWTP, with its physiological characteristics like cell morphology, growth rate, mode of nutrition, and influence factors investigated. Moreover, we obtained its completed genome sequence, and predicted its potential functions based on genome annotations. This strain is affiliated with the previously proposed wastewater cluster B\textsuperscript{7}, a cluster specific for activated sludge reactors and is detected frequently in different WWTPs. The strain SAT1, as a representative AOA from wastewater, the research findings on it will extend our understanding on AOA occurrence and functions in WWTPs and may lay foundation for their future application.

**Results**

**Establishment of highly purified AOA enrichments.** By using activated sludge from a full-scale WWTP as initial inoculums, AOA enrichment culture was established. Antibiotics including 50 mg/L ampicillin and 25 mg/L streptomycin were used. A long time (about 10 weeks) was needed for complete consumption of about 0.3 mM ammonia in initial cultivation, but it was shortened to about 3 weeks after the second transfers (Supplementary Fig. S1). The successful PCR amplification of archaeal 16S rRNA and amoA gene indicated the presence of AOA. After 5–6 transfers, antibiotics were removed from the medium and filter-transferring was used, which further shortened the time of each cycle to 3–4 weeks. After near one year’s enrichment, the culture was used for further analysis.

The absence of AOB in the cultivation system was suggested by negative amplification of bacterial amoA gene using primers (amoA1F/amoA2R, see Supplementary Table S1). Thirty five nearly identical (with sequencing and amplification errors less than 3 nucleotides) archaeal 16S rRNA sequences were identified from the constructed clone library, indicating that only one archaeon was obtained, here referred to as strain SAT1. The uniformity of archaeal 16S rRNA was also checked by Denaturing Gradient Gel Electrophoresis (DGGE) analysis, resulting in only one single band obtained (Supplementary Fig. S2).

The purity of AOA was analyzed by the quantification of archaeal and bacterial 16S rRNA gene within the SAT1 enrichments. Quantitative PCR showed that the archaeal 16S rRNA gene consist of 91% of total prokaryotes (6.68 ± 1.92) × 10\textsuperscript{7} for archaea and (6.25 ± 0.77) × 10\textsuperscript{9} for bacteria), and metagenomic data showed that the ratio was 85% (459 archaeal and 83 bacterial 16S rRNA sequences based on shotgun sequencing and RDP classification), indicating that the strain SAT1 was highly enriched. Attempts to isolate pure strain failed, and the contaminated bacteria were analyzed by 16S rRNA clone library. The dominated bacteria were associated with the genera *Ralstonia* (90%), *Afipia* (3%), *Ohtaekwangia* (3%) and *Tardiphaga* (3%). No AOB or nitrite-oxidizing bacteria (NOB) 16S rRNA sequences were obtained.

Based on 16S rRNA sequence, the strain SAT1 is affiliated with Group I.1a of the phylum *Thaumarchaeota* (Supplementary Fig. S3). The maximum similarity between SAT1 and other reported AOA strain is 96% (with "Ca. Nitrosotenuis chungbukensis"), indicating that SAT1 is a novel strain\textsuperscript{23}. The amoA gene phylogeny of the strain SAT1 is congruent with that of 16S rRNA gene, and it is also affiliated with Wastewater Cluster B (WWC-B), a cluster specific for activated sludge reactors\textsuperscript{7} (Fig. 1).

Unexpectedly, The SAT1 cells were spherically shaped based on SEM and TEM analyses, with diameter of 1.1 ± 0.1 μm (Fig. 2). The cell shape of SAT1 is similar to that of Group I.1b AOA\textsuperscript{18,24}, but different from other Group I.1a strains, which were all rod shaped\textsuperscript{4,17,25,26}.

**The growth and autotrophy of the strain SAT1.** The growth curve of strain SAT1 were demonstrated by its cell abundance together with the decrease of initial ammonia concentration coupled to exponential increases of nitrite concentration (Fig. 3a). The cell abundances were represented by archaeal 16S rRNA and amoA gene copies detected by quantitative PCR. The maximum growth rate, estimated from 16S rRNA gene abundance, was 0.25 d\textsuperscript{-1} (with doubling time of 2.9 d), which was comparable to that of *Nitrososphaera* sp. JG1\textsuperscript{24}, but lower than most of the other AOA strains. The cell ammonia oxidation activity was estimated as 3.8 fmol cell\textsuperscript{-1} d\textsuperscript{-1}, which was higher than that of *Nitrososphaera* sp. JG1 (1.4 fmol cell\textsuperscript{-1} d\textsuperscript{-1}) and "Ca. Nitrosoarchaeum koreensis" (2.5 fmol cell\textsuperscript{-1} d\textsuperscript{-1}), but lower than that of *Nitrosopumilus maritimus* (12.8 fmol cell\textsuperscript{-1} d\textsuperscript{-1}).

The carbon fixation ability of strain SAT1 was determined using stable isotope probing (SIP). Duplicated incubations were performed for 2 cycles of cultivation (approx. 4 weeks per cycle) in the presence of 2.5 mM 1\textsuperscript{13}C-NaHCO\textsubscript{3} or 1\textsuperscript{13}C-C\textsubscript{5}H\textsubscript{4}O\textsubscript{2}. Ammonia oxidation was indicated by decreases in ammonia concentration and increases in nitrite concentration and amoA gene copies as usual cultivation without NaHCO\textsubscript{3}. After completely consumption of ammonia, the media were used for genomic DNA extraction and gradient centrifugation. The relative proportion of archaeal amoA gene copies in CsCl gradients was determined by quantitative PCR of three replicates. The archaeal amoA genes reached the maximum value around a buoyant density of 1.67 g ml\textsuperscript{-1} under 1\textsuperscript{13}C-NaHCO\textsubscript{3} treatment for both of the 2 cycles’ incubation. For 1\textsuperscript{13}C-NaHCO\textsubscript{3} treatment group, the maximum archaeal amoA genes value shifted to around a buoyant density of 1.71 g ml\textsuperscript{-1} after the first cycle of incubation, and further shifted even heavier after the second cycle (Fig. 3b). Although the buoyant densities as a whole were lower than the standard ones, a difference of 0.04 g ml\textsuperscript{-1} fitted well with those between unlabeled and fully labeled 1\textsuperscript{13}C-DNA\textsuperscript{27}. Thus, the ability of incorporating 1\textsuperscript{13}C-NaHCO\textsubscript{3} into DNA indicated that the strain SAT1 could grow autotrophically.
The influences of environmental factors on strain SAT1. For each environmental factor, the influences were determined by comparing the specific growth rates of AOA under gradient conditions. As for salinity, gradient concentrations of NaCl ranging from 0.005%–0.1% were used. It was shown that the strain SAT1 could adapt only to salinity no higher than 0.03% (~647 μS cm$^{-1}$ in electrical conductivity) (Fig. 4a). It had a much lower salinity tolerance than any other reported AOA strain such as *“Ca. Nitrosoarchaeum koreensis”* (0.4%)$^{25}$ and *Nitrosopumilus maritimus* (>3.5%)$^{15}$. However, strain SAT1 was tolerant to salinity as low as 0.005% (~90 μS cm$^{-1}$), which was even lower than that of common wastewater. This value was comparable to

Figure 1. Phylogenetic tree showing the relationships of *amoA* gene sequence of strain SAT1 to reference sequences from the GenBank database. The tree was constructed with the neighbor-joining method. Bootstrap values shown at nodes where the value was greater than 50, are based on 1000 trials. For sequences inside wastewater cluster B, those from wastewater treatment plant were marked with circles (●), those from freshwater rivers/lakes were marked triangles (▲), and those from drinking water treatment plant were marked block (▭).

Nitrite 1.74 
Ammonia C (1) 

Nitrosopumilus maritimus limits were comparable with Nitrosotenuis". Ca.
S6), suggested that strain SAT1 was a novel AOA species within the genus of "Ca.
uzonensis" (Supplementary Table S4). These evidences together with the genomic phylogeny (Supplementary Fig.
resulting in lower identities: 68.88% with "Ca.
Chungbukensis" 26) and AOB (100 μM for "Ca.
500 μM)25, and much higher than other AOA strains (100 μM for "Ca.
Nitrosoarchaeum koreensis"-20, but lower than that of Nitrosotalea devanaterra (up to 50 mM)20. The strain SAT1 was adapted to temperature from 25 °C to 33 °C, and the optimum was 29 °C (Fig. 4d). The pH range was 5.0 to 7.0, with the optimum pH at 6.0 (Fig. 4e). These properties indicated that the strain SAT1 was mesophilic and neutrophilic.

The inhibition of allylthiourea (ATU) to the SAT1 was tested. No inhibition was observed when ATU concentration was lower than 100 μM, partial inhibition occurred at 500 μM, and complete inhibition at 700 μM (Fig. 4f). This inhibition concentration for the SAT1 was high, only comparable to that of "Ca. Nitrosoarchaeum koreensis" (>500 μM)25, and much higher than other AOA strains (100 μM for Nitrosoarchaeum sp. JG123, and 50 μM for "Ca. Nitrosoarchaeum chungbukensis"-20) and AOB (<10 μM25). Since ATU could chelate Cu++, the higher inhibition concentration demonstrated that the strain SAT1 had a higher affinity for Cu++, which might result from the high content of copper-containing protein in its genome (see below).

The general features of SAT1 genome. High-throughput sequencing based on 500 bp and 5-kb libraries was performed. After sequence filtration, assembling and gap closing, a complete genome of the strain SAT1 was reconstructed (see Supplementary Fig. S4). The genome size was 1620156 bp, including 1717 protein coding genes in this genome were nearly identical (with sequencing and amplification errors less than 3 nucleotides) to that obtained from clone library before.

When aligning genomes using MUMmer 3.0, similar genome syntenies were observed between the SAT1 and other Group I.1a AOA except "Ca. Cenarchaeum symbiosum", no large syntenic regions were observed between the SAT1 and Group I.1b genome (Supplementary Fig. S5). It was noted that there was a remarkable inversion of large DNA fragment in the genome of SAT1 when comparing with Group I.1a strains (Supplementary Fig. S5a), which was never found in other AOA genomes. The inverted fragment was from the site of around 0.3 Mb to 1.4 Mb, about 1.1 Mb in size, and accounted for 68% of the entire genome. It might be caused by recombination during the evolution of the strain SAT1. Similar large fragment chromosome inversions were also observed in some other bacterial strains like Staphylococcus aureus28 and Bacillus anthracis CDC 68410, which resulted in their reduced cell growth compared with closer strains without inversion. Thus, it was likely that the relatively low growth rate of the strain SAT1 was caused by the chromosomal inversion.

Comparing to other known AOA strains, the SAT1 had the largest genomic average nucleotide identity (ANI) of 75.49% with "Ca. Nitrosoarchaeum chungbukensis" and 75.11% with "Ca. Nitrosotenuis uzonensis" (Supplementary Table S4), which is far below the threshold for species demarcation (95–96%)32. Since ANI values below 75% are not to be trusted, the average amino acid identity (AAI) was calculated based on protein sequence, resulting in lower identities: 68.88% with "Ca. Nitrosoarchaeum chungbukensis" and 73.76% with "Ca. Nitrosotenuis uzonensis" (Supplementary Table S4). These evidences together with the genomic phylogeny (Supplementary Fig. S6), suggested that strain SAT1 was a novel AOA species within the genus of "Ca. Nitrosotenuis".

Nitrogen metabolism characteristics of the strain SAT1. Putative genes encoding ammonia monooxygenase were found in the genome of the SAT1 with its subunits arranged in the same order (amoB-amoC-amoX-amoA, Supplementary Fig. S7; SU86_008310-SU86_008325 in Supplementary Data.
S1) as other Group I.1a AOA^{22,26,33}. Additionally, two ammonia transporters genes (amtB, SU86_004840 and SU86_005670) were identified.

As all other known AOA, no homologs for bacterial hydroxylamine oxidoreductase (HAO) gene were identified in the genome of the strain SAT1. However, as proposed by Walker et al., numerous multicopper oxidases (MCOs) and small blue copper-containing proteins might take the roles of the missing HAO and cytochrome c protein, respectively^{22}, thus suggest an alternative ammonia oxidation and electron transfer pathway via hydroxylamine^{34}. Two MCOs were identified in the genome of the SAT1, and one of which (SU86_009190) was NO-forming nitrite reductase protein (NirK). NirK was also involved in the reduction of NO\textsubscript{2} to NO, and

---

**Figure 4.** Influence of (a) salinity, (b) ammonia, (c) nitrite, (d) temperature, (e) pH and (f) Allylthiourea on the growth activity of strain SAT1. Values represent percentage of specific growth rates of cultures grown under different environmental values relative to those at optimal ones. Error bars represent the standard deviations of triplicate cultures.
probably play an important role in N\textsubscript{2}O production. But the downstream genes, encoding nitric oxide reductase subunits (Nod/NorQ), which were present in the genome of "Ca. Nitrososphaera evergladensis" were absent in that of SAT1. Thus production of N\textsubscript{2}O by the strain SAT1 remains elusive. Besides, seven small blue copper-containing proteins were identified (Supplementary Data S1). One of which (SU86_000100) contained three cupredoxin domains, which might be a candidate for quinone reductase (QRED) as in \textit{Nitrosopumilus maritimus}.

Urea was an alternative nitrogen and energy source for some AOA strains such as \textit{Nitrososphaera viennensis}\textsuperscript{18}, "Ca. Nitrososphaera gargensis"\textsuperscript{35} and "Ca. Cenarchaeum symbiosum"\textsuperscript{36}, with urease and urea transporter gene identified in their genome (Supplementary Table S3). For the SAT1 genome, genes coding for urease core proteins (\textit{UreC, UreB, UreA}, locus tag in Supplementary Data S1) and urease accessory proteins (\textit{UreE, UreF, UreG, UreD}) were identified (Fig. 5a). However, no completed urea transporter gene was found, except that a pseudogene (SU86_09525), 457 ORFs far from urease gene cluster, was identified as a combination of a C-terminal truncated urea transporter and an N-terminal truncated histidine kinase. This truncated urea transporter, which was caused by gene combination during evolution, might have already lost its functions. To confirm this, we use urea, instead of ammonia, as substrate in cultivation of AOA. After one cycle of normal incubation (about 25 days), no increase on the nitrite concentration or cell abundance was observed comparing with those using ammonia as substrate (Fig. 5b), and it remained the same when further extending the incubation time to two months. These results indicated that the strain SAT1 had lost the ability of urea utilization due to the truncation of urea transporter gene.

**Figure 5.** (a) Organization of urease utilizing genes of SAT1 genome and (b) the experimental test of its urea utilizing ability. The organization of genes was in comparison with "Ca. Nitrosopumilus sediminis" AR2 (above) and "Ca. Nitrososphaera evergladensis" (below). Urease core protein genes were shown in red, urease accessory protein genes were shown in blue, urea transporter (UT) genes were shown in green, and histidine kinase (HK) genes were shown in orange. For comparison, forward matches colored in red and reverse matches colored in green. The numbers between two genes indicated the number of interval ORFs. For the test of the urea utilizing ability of SAT1, the nitrite production and archael 16S rRNA abundance during one cycle of incubation, using 0.5 mM NH\textsubscript{4}\textsuperscript{+} (purple line and blue column) and 0.25 mM Urea (light green line and red column) as substrate respectively.
Carbon metabolism characteristics of the strain SAT1. In agreement with all of other thaumarchaeal genomes\textsuperscript{22,35}, the SAT1 genome contained all key genes for 3-hydroxypropionate/4-hydroxybutrate (3-HP/4-HB) cycle (Supplementary Data S1), which was responsible for autotrophic carbon fixation. This cycle was a modified version of the autotrophic hydroxypropionate/hydroxybutyrate cycle of \textit{Crenarchaeota}, and believed to be the most energy efficient pathway than any other aerobic autotrophic pathway\textsuperscript{22,37,38}.

Reductive tricarboxylic acid (TCA) cycle was also used by some autotrophic bacteria for carbon fixation. A near complete reductive TCA cycle could be reconstructed based on related genes of the SAT1 genome (Supplementary Data S1). However, the conversion of citrate to oxaloacetate is uncertain. This step, the so called citrate cleavage, could be accomplished by three ways: catalyzed by citrate lyase (CL, EC 4.1.3.6), ATP citrate lyase (ACL, EC 4.1.3.8), or cyril-CoA synthetase (CCS) followed by citry-CoA lyase (CCL)\textsuperscript{39}. No homologs for genes encoding enzymes for the latter two ways were identified in the SAT1 genome. For the first enzyme CL, it was composed of three subunits: \(\alpha\) (citF), \(\beta\) (citE) and \(\gamma\) (citD), of which only \(\gamma\) (citE) (SU86\_005245) was identified. Whether any unknown proteins in the genome of the SAT1 could substitute the function of citF and citD, and whether the strain SAT1 was capable of fixing CO\(_2\) via reductive TCA cycle need further investigation.

Two key genes coding for subunits of polyhydroxalkanoate (PHA) synthase were identified in the genome of SAT1: \textit{phaC} (SU86\_001140) and \textit{phaE} (SU86\_001145), and shared 48% and 28% similarities respectively with that in \textit{Ca. Nitrosophaera gargensis}\textsuperscript{35}. This enzyme could synthesize poly-3-hydroxybutyrate (PHB), the most common type of PHA, using (R)-specific-3-Hydroxybutanoyl-CoA as monomer\textsuperscript{40}. However, in contrast to its enantiomer, (R)-3-Hydroxybutanoyl-CoA was not involved in thaumarchaeral or crenarchaeral 3-HP/4-HB cycle\textsuperscript{37}. It could only be converted from the inversion of (S)-3-Hydroxybutanoyl-CoA by an epimerase, or from crotonoyl-CoA, another 3-HP/4-HB cycle intermediate, by (3R)-3-Hydroxybutanoyl-CoA dehydratase as in \textit{Rhodospirillum rubrum}\textsuperscript{41}. In the genome of the SAT1, only homologues of one of these enzymes were identified (\textit{phaD}, SU86\_006950), and this enzyme was present only in \textit{Ca. Nitrososphaera limnia}\textsuperscript{BG20} and \textit{Ca. Nitrosotenus chungbukensis} MY2, not in other thaumarchaeal genomes. These results indicated that these strains might take a distinct PHA synthesis pathway using crotonoyl-CoA as starting materials, but it need to be experimentally confirmed.

Other important genomic features of the SAT1. Genes coding for flagella, chemotaxis and pili were identified in the genome of the SAT1 (Supplementary Data S1). Similar to \textit{Ca. Nitrosoarchaeum limnia}\textsuperscript{SFB1}, five copies of flagellin subunit coding genes (\textit{flaB}) were found in the SAT1 genome, while only 1–2 copies were observed in other AOA genome\textsuperscript{40,35}. However, we did not observe defined flagella from the strain SAT1 using TEM. Since flagella were relatively large motility organelles for the cell, the formation of the flagella and the expression of their components were regulated by environmental conditions\textsuperscript{41}. Lower expression of flagella in certain environments had been reported in some prokaryotes like \textit{Vibrio spp.} and \textit{Escherichia coli}\textsuperscript{42,43}. Thus, it was possible that the expression level of flagella genes of strain SAT1 was low in our lab environment, which made its flagella hard to be observed. To prove this, further studies on the morphology of strain SAT1 in WWTPs environments are needed in the future.

Various genes related to heavy metal and antibiotics resistant were identified in the SAT1 genome (Supplementary Data S1), while no CRISPR region was found. Heavy metal included copper, arsenic, tellurium, cobalt, zinc, and cadmium could be pumped out of the cell by related transporters. Among them, the cobalt-zinc-cadmium efflux system protein (SU86\_005285) was non-homologous to the same efflux protein occurred in \textit{Ca. Nitrososphaera evergladensis}\textsuperscript{40}, and absent from other AOA strains. Antibiotic resistance proteins included transporters and potential antibiotic degradation enzymes. Interestingly, a gene coding for cephalosporin hydroxylase was found, which was absent from other cultivated AOA strains, and was only found in the single-cell extracted AOA \textit{Ca. Nitrosoarchaeum limnia} BG20 and a metagenomic shotgun sequencing project \textit{thaumarchaeote} SCGC AAA799-P11 (JOSZ00000000, unpublished). Estimated from the phylogenetic tree (Supplementary Fig. S8), this hydroxylase might be horizontally transferred from \textit{Cyanobacteria} or \textit{Pseudomonas} spp. Since the strain SAT1 was the only cultivated AOA possessed this gene, potential cephalosporin degradation activity should be examined in the future.

Discussions

The SAT1 was the first cultivated AOA strain from WWTPs, which was affiliated with Wastewater Cluster B (WWC-B) based on its \textit{amoA} gene phylogeny: This cluster was firstly proposed by Park \textit{et al.}\textsuperscript{7}, and AOA of this cluster was detected in a list of WWTPs across the world (Supplementary Table S5), suggesting a significant role in nitrogen removal in those plants. By far, the strain SAT1 was the only AOA enrichment of WWC-B, thus the study on its physiology and genome can greatly improve our understanding on the occurrence and function of this cluster in WWTPs. Based on the results above, it was possible that there were some intrinsic features made strain SAT1 suitable for WWTPs environment.

The first significant physiological feature of strain SAT1 shown in this study was its intolerance to high salinity. This could be partially explained by the genomic data. Most prokaryotes coped with high salinity (osmosis) by synthesizing compatible solutes, which were usually some highly soluble organic molecules that could help balance the intra- and extra-cellular osmotic pressure. In archaea, a list of compatible solutes was used for high osmosis response, including ectoine/hydroxyectoine, mannosylglycerate, di-myoinositol phosphate (DIP), etc.\textsuperscript{44,45}. Ectoine/hydroxyectoine were synthesized from L-aspartate-\(\beta\)-semialdehyde, with four enzymes (EctB, EctA, EctC and EctD) participating in that process (Supplementary Fig. S9a)\textsuperscript{46}. Genes coding for these four enzymes were all found in the genome of \textit{Nitrosopumilus maritimus}\textsuperscript{22} (Supplementary Table S3), which facilitated its adaptation to salinity higher than 3.5%, but absent from the genome of the SAT1. Mannosylglycerate could be used for high osmosis and heat stress protection, and it is synthesized from 3-phosphoglycerate and GDP- mannose via a two-step pathway (Supplementary Fig. S9b)\textsuperscript{47}. Two genes responsible for this pathway were

\[ \text{GDP- mannose} \rightarrow \text{D-mannose} \rightarrow \text{Ectoine} \]

\[ \text{GDP- mannose} \rightarrow \text{D-mannose} \rightarrow \text{Hydroxyectoine} \]
identified in “Ca. Nitrososphaera gargensis” and “Ca. Nitrososphaera evergladensis” but not in the genome of the SAT1. DIP was the third compatible solute used by Group I.1b AOA, its complete synthesis required four enzymes (Supplementary Fig. 5c). However, only the first enzyme was identified in the genome of the SAT1, thus made this pathway infeasible. On the other hand, the strain SAT1 could live in low salinity environment (0.01%, Fig. 4), which might result from the containing of large-conductance mechanosensitive channel (MscL) concentration, lowered the osmotic driving force for water entry, and protected the cells against lysis. This channel was present in the genomes of a nearby low-salinity adapted AOA “Ca. Nitrosotenuis uzonensis” and another low salinity strain “Ca. Nitrosocarchaeum limnia” SFB1, but absent from the genome of Nitrosopumilus spp. strain, which lived mainly in high-salinity marine environment. Therefore, due to lack of key genes for three usual compatible solutes synthetic pathways and the presence of MscL channel, the living conditions of strain SAT1 were restricted to low salinity environment. For WWTPs, they were usually low in salinity (defined as < 1% according to Kargi et al.), except those for contaminated groundwater and in filtration of sea water, which would be suitable for strain SAT1. Similar salinity tolerant values and mechanisms might be used by WWC-B cluster strains, since most of them also lived in low-salinity environments like freshwater rivers and lakes as shown in Fig. 1, and they were phylogenetically related to the strain SAT1.

Another important feature which helped strain SAT1 adapt to WWTPs environment might be their possession of flagella. Besides cell mobility, archaeal flagella and pili played a central role in surface adhesion and the formation of cell-cell connections, and thus could facilitate the formation of biofilms as observed in Euryarchaeota strains like Pyrococcus furiosus and Methanothrix volcanoethic. Although not as dense as those two Euryarchaeota strains, the flagella of Thaumarchaeota might also contribute to biofilm formation, which was especially significant for their survival in WWTPs. The relative low growth rate of Thaumarchaeota suggested that they could easily be washed out from WWTPs if lived dispersedly. On the contrary, if attached to the biofilms, the cell loss would be slow. This was evident from the low diversities of AOA communities in WWTPs. Several surveys had demonstrated that Group I.1b (mainly wastewater cluster D) AOA were the most dominant in WWTPs, then was WWC-B within Group I.1a, but Nitrosopumilus spp. AOA were rarely found. Taking genomic properties into consideration, the former two clusters all contained genes coding for flagella and pili, while Nitrosopumilus spp. AOA were lack of them. It was possible that due to the lack of flagella and pili, Nitrosopumilus spp. AOA lived dispersedly, independent of biofilms, just as they did in marine environments, which rendered them difficult to retain in WWTPs with relatively higher flow rate. Moreover, WWC-B strains were usually found in plants with biofilm process or granule sludge process. That might come from the easier biofilm formation abilities of this cluster, which would extend their retention time.

In summary, the low salinity adaptation and flagella and pili might help strain SAT1 adapt to artificial WWTPs environment. Similar mechanisms might be used for the nearby WWC-B strains. Once entered the biological reactors along with the wastewater influent, those strains would be able to stay and grow there and through artificial selections finally became a significant AOA cluster in WWTPs. In addition, the AOA of WWC-B cluster reactors along with the wastewater influent, those strains would be able to stay and grow there and through artificial selections finally became a significant AOA cluster in WWTPs. Similar salinity tolerant values and mechanisms might be used by WWC-B cluster strains, since most of them also lived in low-salinity environments like freshwater rivers and lakes as shown in Fig. 1, and they were phylogenetically related to the strain SAT1.

**Methods**

**Cultivation of AOA.** A total of 5 ml activated sludge were added as inoculum to 50 ml medium in 120 ml serum bottles, and then sealed with rubber stoppers and aluminum caps (CNW technologies, USA). The medium was composed of NH₄Cl (0.5 mM) and KH₂PO₄ (0.1 mM), no NaHCO₃ or other salt was necessary in usual incubation. After autoclaving, 50 µl trace element solution (1000 x) was added. Antibiotics were used to select against the cocultured bacteria in the initial phase (the first 4 to 5 transfers) of the enrichment, including ampicillin (50 mg/L) and streptomycin (25 mg/L), and replaced by filter-transferring after stable AOA enrichment was
Cloning, sequencing, and phylogenetic analysis. Cells were harvested from the enrichment culture by passing through a 0.2 μm GTTP membrane (Millipore, USA), immediately frozen and stored at −80 °C until further analysis. DNA was extracted using a FastDNA SPIN Kit for soil (MP Biomedicals, USA) following the manufacturer’s protocol. The concentration of DNA was determined using Nanodrop spectrophotometer ND-1000 (ThermoFisher Scientific, USA). The bacteria and archaeal 16S rRNA and amoA genes were amplified by PCR using the primers listed in Supplementary Table S1 in the supplemental material. All the PCR conditions were as follows except bacterial amoA gene: 94 °C for 5 min; 35 cycles of 94 °C for 30 s, 55 °C for 30 s, and 72 °C for 30 s; and 72 °C for 10 min. For bacterial amoA gene, a condition of 94 °C for 2 min; 35 cycles of 94 °C for 40 s, 51 °C for 60 s, and 72 °C for 60 s; and 72 °C for 5 min was used. Cloning into pGEM-Teasy vector (Promega, USA) and sequencing with T7 and SP6 vector primers was performed using standard procedures. Phylogenetic analysis of archaeal 16S rRNA and amoA gene was performed by using MEGA version 5.224, and the neighbor-joining tree was constructed using Maximum Composite Likelihood method. Bootstrap value of 1,000 replicates was set to estimate the reliability of phylogenetic reconstruction.

Quantitative PCR. Archaeal and bacterial 16S rRNA and amoA genes copy numbers were quantified using an iCycler iQ5 thermocycler (Bio-Rad, USA), with the primer listed in Supplementary Table S1. Quantification was performed in 25 μl volume containing 12.5 μl SYBR Premix Ex Taq (Takara, Japan), 0.4 μM of each primer and 0.2 mg ml−1 BSA. The thermal cycling conditions for archaeal and bacterial 16S rRNA genes were as follows: 95 °C for 5 min; 40 cycles of 95 °C for 10 s, 51 °C for 30 s, and 72 °C for 30 s; and 72 °C for 30 s. The conditions for archaeal amoA gene were similar, except for using 55 °C as annealing temperature. Readings were taken between each cycle. Standard curves were prepared using pGEM-T Easy Vector ligated with reference genes (KP282616 for archaeal amoA gene, KP004891 for archaeal 16S rRNA gene, and KR815497 for bacterial 16S rRNA gene), as previously described by Ding et al.37. The efficiencies of all the assays ranged from 95.6% to 103.4% with the R2 at least 0.991. The specificity of quantitative PCR was checked by analyzing the melting curves.

Stable isotope probing fractionation. For SIP incubation, AOA subcultures were additionally supplemented with 2.5 mM NaH13CO3 (99 atoms%) was purchased from Sigma-Aldrich (USA) Co. After one cycle of incubation, 10% of the medium was used as inoculation for a new cycle, and the rest were all used for DNA extraction. Two cycles of incubation with two replicates were performed totally. Extracted DNA (~2 μg) was added into CsCl gradients with an initial density of 1.696 g ml−1. Density gradient centrifugation was performed in 4.9 ml OptiSeal polyallomer tubes (Beckman Coulter, USA) in a VTi 90 vertical rotor, subject to centrifugation at 56200 rpm for 24 h at 20 °C25. Centrifuged gradients were fractionated into 24–25 equal volumes (~200 μl) as described in detail by Zhang et al.39. Nucleic acids were precipitated by using PEG 6000, and then dissolved in 30 ml of TE buffer.

Electron microscopy analyses. For scanning electron microscopy (SEM) analysis, AOA cells were harvested using 0.22 μm polycarbonate GTTP membrane (Millipore, USA), and then fixed in 2.5% (vol/vol) glutaraldehyde in 0.1 M sodium phosphate buffer (pH 7.2) for 24 h at 4 °C, and dehydrated using a graded ethanol series (70 to 100%) and finally 100% tertiary butanol. The samples were examined with a Quanta 200 electron microscope (FEI, the Netherlands). For transmission electron microscopy (TEM) analysis, cells were collected from 500 ml of culture by centrifugation at 6000 g for 10 min, and then negatively stained with 1% (wt/vol) phosphotungstic acid. Ultrathin sections were produced with an EM UC6 ultramicrotome (Leica, Germany), stained with uranyl acetate and lead citrate, and examined with an H-7650B electron microscope (Hitachi, Japan).

Genome sequencing and analysis. DNA for genome sequencing was extracted using PowerSoil DNA Isolation Kit (MO BiO, USA) from 500 ml culture of strain SAT1. Two DNA libraries were constructed: a paired-end library with an insert size of 500 bp and a mate-pair library with an insert size of 5 kb. Both libraries were sequenced using an Illumina HiSeq2500 by PE125 strategy. Library construction and Sequecing was performed at the Beijing Novogene Bioinformatics Technology Co., Ltd. Illumina PCR adapter reads and low quality reads were filtered using in-house program. The archaeal and bacterial communities of Metagenomic DNA were analyzed using MG-RAST online tools60. The filtered reads were assembled by SOAPdenovo 61, which finally resulted in one completed scaffold of 1.6 Mb. Gene prediction was performed on the SAT1 genome assembly by GeneMarkS62 with integrated model which combine the GeneMarkS generated (native) and Heuristic model parameters. Transfer RNA (tRNA) genes were predicted with tRNAscan-SE63. Ribosome RNA (rRNA) genes were predicted with rRNAmmer64. A whole genome Blast search (E-value less than 1e-5, minimal alignment length percentage larger than 40%) was performed against 3 databases. They are KEGG (Kyoto Encyclopedia of Genes and Genomes)65, COG (Clusters of Orthologous Groups)66, and NR (Non-Redundant Protein Database). Comparison of the SAT1 and other AOA genome was performed using MUMmer 3.067. The average nucleotide identity (ANI) and average amino acid identity (AAI) was calculated online (http://enve-omics.ce.gatech.edu/ani/)68,69.

Acknowledgements
This study was supported by the NSFC (51078207, 51178239), and the special fund of the State Key Joint Laboratory of Environmental Simulation and Pollution Control (14LO3ESPC).

Author Contributions
Y.L. carried out the enrichment, physiological experiments, analyzed the genome sequence and wrote the manuscript draft. K.D. carried out the SIP and EM experiment, and analyzed the genome sequence. X.W. was the experiment designers, supervised the data analysis and revised the manuscript. B.Z. and B.S. performed sampling for enrichment and carried out the growth and environmental factors experiments. Y.Y. revised the manuscript and improved the English language. All authors read and approved the final manuscript.

Additional Information
Accession numbers: The genome sequence of the SAT1 had been deposited in GenBank under Accession No. CP011097.2. The 16S rRNA gene and amoA gene sequence of the SAT1 obtained from PCR-based clone libraries were under Accession No. KP04891 and KP282616.
