The non-equilibrium random-field Ising model is well studied, yet there are outstanding questions. In two dimensions, power law scaling approaches fail and the critical disorder is difficult to pin down. Additionally, the presence of faceting on the square lattice creates avalanches that are lattice dependent at small scales. We propose two methods which we find solve these issues. First, we perform large scale simulations on a Voronoi lattice to mitigate the effects of faceting. Secondly, the invariant arguments of the universal scaling functions necessary to perform scaling collapses can be directly determined using our recent normal form theory of the Renormalization Group. This method has proven useful in cleanly capturing the complex behavior which occurs in both the lower and upper critical dimensions of systems and here captures the 2D NE-RFIM behavior well. The obtained scaling collapses span over a range of a factor of ten in the disorder and a factor of $10^4$ in avalanche cutoff. They are consistent with a critical disorder at zero and with a lower critical dimension for the model equal to two.

We study the avalanche size distribution in the two-dimensional nucleated non-equilibrium random-field Ising model (NE-RFIM), simulated on a Voronoi lattice to bypass faceting, and analyzed using the scaling predictions of the nonlinear renormalization-group flows predicted for the lower critical dimension. We find excellent agreement over a large critical region, addressing several outstanding issues in the field.

The NE-RFIM is perhaps the best-understood model of crackling noise [1], exhibiting power-law distributions of avalanche sizes at a critical disorder $r_c$, representing the standard deviation of the strength of the random field at each site. The model transitions from a ‘down-spin’ state to an ‘up-spin’ state as an external field $H$ increases. Above the critical disorder $r_c$, this transition is composed of avalanches of spins of size limited by a typical cutoff $\Sigma_+(r)$; below the critical disorder a finite fraction of the spins flip in a single event, with precursors and aftershock sizes limited by $\Sigma_-(r)$. This model, albeit simple, contains the necessary ingredients to describe hysteretic and avalanche behaviors in a diverse set of systems. Barkhausen noise in magnets [2], decision making in socio-economics [3], absorption and desorption in superfluids [4, 5] as well as the effects of nematicity in high $T_c$ superconductors [6, 8] can each be understood in terms of ‘crackling noise’ naturally described by the NE-RFIM.

Although the NE-RFIM itself has been around in various forms since the 1970s [9], there are still a number of current questions and issues:

- Is it in the same universality class as the equilibrium RFIM model [10]? It has long been debated whether the equilibrium and non-equilibrium versions of the model are in the same universality class. This question of universality has been approached in a number of ways which have suggested the same class for the two models [11-16]. Recent work using the non-perturbative RG indicate that the two models are in different universality classes in lower dimensions [16]. Our findings pretty clearly imply they are also different in two dimensions.

- Is the lower critical dimension (LCD) two, or is power law scaling sufficient to capture the behavior in $D = 2$? The equilibrium RFIM has been shown to have a LCD equal to two [17], and the same is believed to be true for the front-propagation variant of the NE-RFIM [18]. For the nucleated model we study here, some suggest that the LCD is two [19, 20], others suggest that power-laws are indeed able to capture the behavior and no crossover occurs in 2D [21, 22], and some suggest that a lower critical dimension does not exist for this model [23, 24]. Here, we derive the expected non-power-law scaling in the LCD from a nonlinear renormalization-group analysis, and find excellent agreement with the data presuming an LCD of two, while power-law scaling fails to capture the behavior.

- Is the value of the critical disorder in $D = 2$ zero, or positive? In the nucleated model, the critical disorder appears to decrease with dimension, going from $5.96 \pm 0.02$ in 5D to $2.16 \pm 0.03$ in 3D [23]. This behavior in conjunction with the observation that for both the equilibrium and front-propagation problems, $r_c$ is found to be zero [18] suggests that $r_c$ may be quite small. Early work on the nucleated model, presuming power law scal-
ing \cite{20,28,29}, yielded positive $r_c = 0.75 \pm 0.03$ \cite{28}, but more recent work on larger systems finds a smaller $r_c = 0.54 \pm 0.02$ \cite{21,22} collapsing over a small range $r \in [0.64, 0.70]$. Our non-power-law scaling form would predict that power-law fits at a given system size should succeed in small ranges of disorder, but that larger system sizes will yield lower and lower predicted critical disorders. Our results are compatible with a critical disorder of zero, directly (random field strength

orders. Our results are compatible with a critical disorder

tem sizes will yield lower and lower predicted critical dis-
succeed in small ranges of disorder, but that larger sys-
tem sizes will yield lower and lower predicted critical disorders. Our results are compatible with a critical disorder of zero, directly (random field strength $r_c = 0$) or perhaps more naturally in conjunction with some random bond disorder (so $r_c < 0$, see Appendix B 3).

Scaling collapses (e.g. Figs 3 and 4) are the gold standard for identifying universal scaling behavior at critical points. Commonly used in simulations and experiments, the scaling form for a function of two variables usually becomes a power law times a universal function of the ratio of two power laws – a result which follows from linearizing the renormalization-group (RG) flows. The LCD, however, is precisely the dimension at which one of the eigenvalues of the RG flow vanishes and the nonlinear terms become crucial to the behavior. Recently, Raju et al. \cite{30} analyzed non-linearities in renormalization group flows using normal form theory drawn from the dynamical systems community. In the cases for which power laws work well, the dynamics are governed by a hyperbolic fixed point which can be linearized by a change of variables, leading to traditional scaling predictions. Our simulations indicate that the LCD for the NE-RFIM is poised at a transcritical bifurcation in the RG flow. By considering the form the flow equations should take, we are able to provide concrete non-power-law invariant scaling variables which enable collapse of our data over a range of a factor of ten in the disorder. This success, and the enormous critical region, suggests that using the appropriate invariant scaling variables can be effective for analyzing experiments and simulations systems at their LCD (like the XY model), despite exponentially growing correlation lengths. (Similar analyses have been done for the 4-state Potts model \cite{31} and the XY model \cite{32}, except that their invariant scaling variables include only their predicted leading log corrections.)

In addition to the application of our normal form theory of the Renormalization Group, another key component to the success of our collapses is an approach to dealing with the faceting. Running simulations on a square lattice leads to distortions in the shape of the distributions of interest due to lattice effects as the critical point is approached. Long, unnaturally straight avalanche boundaries for small disorder arise which serve to effectively decrease the simulation size (Appendix B 1). To combat this, we run our simulations on a Voronoi lattice. Although this introduces some intrinsic disorder (Appendix B 2), we find the Voronoi lattice to be effective in combating faceting effects, enabling clean collapses over a range of a factor of ten in the disorder, a significantly larger range than the current available collapses which use data in a range $\approx 10\%$.

The paper is organized as follows. In Section I, we define the model we will use in detail. In Section II A, we work out the normal form of the RG flows. In Section II B, we derive the invariant scaling combinations used for the scaling collapses. We discuss the efficacy of our scaling collapses, our ability to fit parameters and alternative choices of scaling forms in Section III before concluding.

## I. MODEL DEFINITION

The non-equilibrium random-field Ising model (NE-RFIM) consists of Ising spins $S_i = \pm 1$ connected by bonds of strength $J = 1$, subject both to a random field $h_i$ and an external field $h_{\text{ext}}(t)$:

$$\mathcal{H} = -\sum_{\langle ij \rangle} JS_i S_j - \sum_i S_i (h_{\text{ext}} + h_i).$$

(1)

The external field starts at $h_{\text{ext}}(t) = -\infty$ and grows until all spins have flipped from $S_i = -1$ to $+1$. The spins flip when they can decrease the energy $H$, triggered either by an increase in the external field $h_{\text{ext}}(t)$ (spawning a new avalanche), or by being kicked by the spin flip of a neighbor (propagating an existing avalanche). The random fields are chosen from a distribution $p(h)$ with zero mean and a width $r$ describing the strength of the disorder from the random field. The simulations in this work use the traditional Gaussian form for the disorder, $p(h_i) = (1/\sqrt{2\pi r^2}) \exp(-h_i^2/2r^2)$. At large disorder $r$ the avalanches are all small; as the disorder decreases the avalanches grow in size (Fig. 1). Avalanche size is denoted by $s$. There are two different variants of the

![FIG. 1: $r = 0.5, 1.0, 5.0, 50.0$ from left to right, top to bottom](image)
In the equilibrium model, the flow equation is found to be \( \frac{dw}{d\ell} = -\frac{\epsilon}{2}w + Aw^3 + h.o.t. \) where \( \epsilon = D - 2 \) and \( w = r/J \) \[17\]. For the NE-RFIM, however, \( r \) has the symmetry \( r \leftrightarrow -r \) while \( J \) lacks this symmetry due to the external field. This implies \( w \leftrightarrow -w \) and suggests that the RG flow for \( w \) in the NE-RFIM must include a squared order term. (Note that the symmetry \( J \leftrightarrow -J \) for the equilibrium Hamiltonian is only valid for systems with a bipartite lattice. It would be natural to test whether the equilibrium RFIM on a triangular lattice retains the pitchfork form \( \log \xi \sim 1/r^2 \) or changes to the transcritical divergence \( \log \xi \sim 1/r \) as suggested by our symmetry argument.)

Assuming the lower critical dimension \( D = 2 \), we have \( \epsilon = 0 \), and may choose a scale for the disorder \( r_s \) such that the prefactor of the squared order term in the flow equation of \( w \) is equal to one. Taking \( J = 1 \), the choice we make for \( w \) is \( w = (r - r_s)/r_s \) where \( r_s \) defines the critical disorder. The generic form for the flow equation of \( w \) is given by

\[
\frac{dw}{d\ell} = w^2 + B_1w^3 + B_2w^4 + \ldots
\]

(Given such a flow equation with an infinite number of possible terms, normal form theory proceeds by systematically removing higher order terms with a change of variables. Consider the change of variables \( w = \tilde{w} + b_1\tilde{w}^2 + b_2\tilde{w}^3 + b_3\tilde{w}^4 + \ldots \). The resulting flow equation takes the form:

\[
\frac{d\tilde{w}}{d\ell} = \tilde{w}^2 + B_1\tilde{w}^3 + (B_1b_1 + b_1^2 + B_2 - b_2)\tilde{w}^4 + \ldots
\]

With an appropriate choice of \( b_1 \) and \( b_2 \), the coefficient of \( \tilde{w}^4 \) may easily be set to zero. Likewise, all higher order terms may be systematically removed. Dropping the tildes and subscripts for clarity, the final form of the flow equation is given by

\[
\frac{dw}{d\ell} = w^2 + Bw^3
\]

which corresponds to the normal form of a transcritical bifurcation \[33\].

Next consider the flow equations for \( s \) and \( h \). The eigenvalues for these are given by \( \lambda_s = d_f \) and \( \lambda_h \) respectively where \( d_f \) denotes the fractal dimension. In each case, the zero eigenvalue of \( w \) gives rise to cross terms between \( s \) and \( w \) and \( h \). Again, in principle, we have an infinite number of possible terms but most all terms may be removed with a polynomial change of variables. The flow equations for \( s \) and \( h \) are hence given by

\[
\frac{ds}{d\ell} = -d_f s - Csw,
\]

\[
\frac{dh}{d\ell} = \lambda_h h + Fhw
\]

where in higher dimensions \( d_f = 1/\sigma \nu \) and \( \lambda_h = \beta\delta/\nu \). In two dimensions, the individual exponents \( \sigma \to 0 \) and \( \nu \) and \( \beta\delta \to \infty \), keeping the combinations we use finite. The coefficients \( B, C, \) and \( F \) are universal. Just as the
linear terms at ordinary (hyperbolic) fixed points yield universal critical exponents, these terms control universal dependences of physical behavior with changes in the control parameters. Note that, while they cannot be set to zero by a coordinate change, they may have universal values equal to zero [34].

B. Invariant Scaling combinations

The appropriate scaling variables to collapse the data can be directly calculated from the flow equations (see Appendix A for full derivation). We may directly solve for the correlation length $\xi \sim (1/w + B)^{-B} \exp(1/w)$ in the normal form variables by integrating Eq. [4] The invariant scaling combination for $s$ obtained takes the form $s/\Sigma(w)$ where $\Sigma(w)$ is a nonlinear function of $w$. We allow for an undetermined scale factor $\Sigma_s$. The resulting form is given by

$$\Sigma(w) = \Sigma_s(B + 1/w)^{-Bf} \exp(df/w).$$

Likewise for $h$, we obtain:

$$\eta(w) = \eta_s(B + 1/w)^{Bh} \exp(-\lambda_h/w),$$

where $(h - h_{\text{max}})/\eta(w)$ is invariant under the RG, and $\eta_s$ is another scale factor.

First consider the area weighted size distribution $A(s|w)$. In analogy with three dimensions, we take $A(s|w) = s^{-1}v_s^2 A(v_s^2)$ where $v_s$ is the scaling variable and the prefactor of $s^{-1}$ arises from normalization constraints with $v_s = s/\Sigma(w)$ from Equation 6. The avalanche size distribution also depends on an unknown universal scaling function, $A$. In order to perform our fits, we choose functional forms for the universal scaling functions. For the area weighted avalanche size distribution, we choose

$$A(v_s) = \frac{1}{A_N} v_s^{a_1} \exp(v_s^{a_2})$$

where the leading power law $v_s^{a_1}$ has been absorbed into $v_s^{a_1}$ here and $A_N$ is the normalization factor $A_N = [\Gamma(\frac{a_1}{2})\gamma(\frac{a_2}{2}, \Sigma(w)^{-2a_2})]/a_2$ where $\gamma$ denotes the regularized upper incomplete gamma function. The associated collapse is shown in Figure 3. The best-fit values of the fitting parameters are $a_1 = 0.6955$ and $a_2 = 1.1057$, which yield an approximation to the universal scaling function $A$ (Fig. 3).

Likewise, in analogy with three dimensions, we obtain $dM/dh(h|w) = \eta(w)^{-1} dM/dh(v_h)$ where $v_h = (h - h_{\text{max}})/\eta(w)$ is the invariant scaling variable. For $dM/dh$ we choose

$$\frac{dM}{dh}(v_h) = \frac{1}{dM/dh_N} \exp \left[ \frac{-v_h^2}{m_1 + m_2 v_h + m_3 v_h^2} \right]$$

where $v_h = (h - h_{\text{max}})/\eta(r)$, and $dM/dh_N$ is a normalization factor computed as a sum of $dM/dh_N$ over the data range. The associated collapse is shown in Figure 4. The best-fit values of the fitting parameters are $m_1 = 0.5748$, $m_2 = -0.1658$, $m_3 = 0.3563$, and $m_4 = 1.3449$, approximating our prediction for the universal scaling function $A$ (Fig. 4).

III. PARAMETER VALUES

Through performing the scaling collapses we are provided with values of $\Sigma$ and $\eta$ for each value of disorder, $r$. Using the nonlinear scaling forms for each of these we may then extract values for the associated parameters. An unconstrained fit yields a fractal dimension larger than two, the dimension of the system, which is unphysical. The 2D avalanches we consider appear compact. This suggests that the fractal dimension should be given by $d_f = 2$ and that the maximum avalanche size should scale as the square of the correlation length. For this reason, we expect also that $\Sigma(w) \sim \xi^2$ and set $C = 0$. Imposing these constraints, the fits obtained are able to
describe the data well, as shown in Figure 5.

As usual, our data is precise enough that the statistical errors in the parameters we estimate are small compared to various systematic errors. The dependence of our estimated $\Sigma(w)$ and $\eta(w)$ on the range of data and functional form appear smaller than the datapoints in Fig. 5. We explore the importance of finite size effects and lattice effects at small and large $r$ by performing the collapses and subsequent fits of the nonlinear forms using subsets of the disorders for which we have data [11 out of 13 points]. The best-fit parameters, with error estimates given by the standard deviation of these measurements, are given in the NF column of Table I. Even larger uncertainties, estimated in the last column, arise from excellent fits that test various conjectures about the parameters.

Note that the best fit value of $r_c$ is found to be less than zero. There are several possible explanations for this. One, $r_c < 0$ could indicate the Voronoi lattice used introduces an amount of intrinsic disorder (Appendix A2). This is certainly plausible as random bond and random field disorder are expected to belong to the same universality class [28, 35]. Alternatively, constraining $r_c = 0$ we obtain a comparable fit by including an alternative normal form, $\text{NF}_{alt}$, differing from $\Sigma(w)$ and by analytic corrections to scaling (expected for the larger disorders considered, see Appendix A3). In either case, the results are consistent with $r_c = 0$.

As a test of our finding that the 2D NE-RFIM corresponds to a transcritical bifurcation, we may compare the fits obtained to those using different underlying assumptions. In particular, it is straightforward to calculate $\Sigma$ and $\eta$ assuming a hyperbolic fixed point (corresponding to power law scaling) and a pitchfork bifurcation (Appendix A4). For each of these cases we can perform a fit to the values of $\Sigma(w)$ and $\eta(w)$ extracted from the collapse. The comparison of these fits are shown in Figure 6.

It is particularly illuminating to consider the behavior of $1/\log \Sigma(w)$. For a transcritical bifurcation, the exponential divergence (ignoring $B$ and $C$ in Equation 9) gives $1/\log \Sigma(w) \sim w/d_f$. Hence, if the behavior corresponds to a transcritical bifurcation, we would expect a plot of $1/\log \Sigma$ to scale linearly with the disorder. A comparison of the linear fit to $1/\log \Sigma$, along with the plots of $1/\log \Sigma$ for the best fits with a power law and pitchfork form are shown in Figure 6. The results clearly support a transcritical bifurcation, perhaps with $r_c < 0$ (Appendix A2), and challenge the alternative power law and pitchfork assumptions.

Simulation data of the 2D non-equilibrium random-field Ising model on a lattice which suppresses faceting is explained well by the presence of a transcritical bifurcation, and is incompatible with power law scaling or pitchfork normal forms without large corrections to scaling. This provides evidence that (1) the universality class of the equilibrium and non-equilibrium models are indeed different and that (2) power law scaling (which is governed by a hyperbolic fixed point) is not the correct approach for this system in this regime. The latter conclusion, in turn, is consistent with (3) the LCD of the model being equal to two, or perhaps close to two.

Although the transcritical bifurcation provides the best description of our simulation data, the corresponding parameter values are difficult to pin down. There are a number of restrictions we can make to the parameter values and still obtain a reasonable joint fit of $\Sigma(w)$ and $\eta(w)$. For example, we may require that the Harris criterion saturates, that $r_c = 0$ [20] or that the coefficient of the quintic order term $B = 0$. Each of these provides a good description of our data. A wide range of fits with various restrictions are shown in Figures 7, 8, 9, and 10. Corresponding best fit parameter values are shown in Tables 11 and 11. As anticipated, the alternative form for the transcritical bifurcation is able to better capture the

---

**FIG. 5:** Comparison of the best fit of $\Sigma(w)$ and $\eta(w)$ derived with different functional forms of $dw/dr$. We have $w = (r - r_c)/s_e$ such that $\Sigma(r) = \Sigma(w)$ and $\eta(r) = \eta(w)$.

'NF' corresponds to $\Sigma$ and $\eta$ derived from the transcritical normal form, 'Power Law' the hyperbolic (power law) form and 'Pitchfork' the pitchfork form.

**FIG. 6:** Comparison of $1/\log \Sigma(w)$ for the best fit of $\Sigma(w)$ derived with different functional forms of $dw/dr$. We have $w = (r - r_c)/s_e$ such that $\Sigma(r) = \Sigma(w)$. 'NF' corresponds to $\Sigma$ derived from the transcritical normal form, 'NF$_{alt}$' to an alternative normal form (Appendix A3) constraining $r_c = 0$. 'Power Law' the hyperbolic (power law) form and 'Pitchfork' the pitchfork form.
TABLE I: Table of the parameter values determined through a joint fit of $\Sigma(w)$ and $\eta(w)$. $NF$ corresponds to the transcritical form and $NF_{alt}$ to the alternative transcritical form described in Appendix A.3. $NF_0$ corresponds to the transcritical form with $rc = 0$ and $NF_{Harris}$ to $\lambda_h = 1$, the Harris criteria. To compute the error bars, we performed the collapses and subsequent fits of the nonlinear forms using subsets of the disorders for which we have data [11 out of 13 points]. The errors given are the standard deviation of the values determined in this way. Values in bold were fixed in the corresponding fit. (Nonuniversal parameters in Tables III and II)

FIG. 8: Fit comparisons $\eta_{th}(w)$, transcritical form

In three and higher dimensions [20, 36], measuring a variety of avalanche properties was crucial in pinning down the universal critical exponents and scaling functions. $dM/dH$ and the cumulative avalanche size distribution, measured here, were supplemented by measurements of finite-size scaling, avalanche correlation functions, avalanche sizes binned in $H$, spanning avalanches, avalanche durations, and average avalanche temporal shapes. Larger system sizes should be possible with improved Voronoi data structures: the intercept of Fig. 6 suggests that a random-field free $r = 0$ simulation of size $L \sim \sqrt{\Sigma(r = 0)} = e^{10} \approx 22,000$ might divide into multiple avalanches at $r = 0$, implying that $rc < 0$.

IV. CONCLUSIONS

In summation, performing large scale simulations on a Voronoi lattice and analyzing the RG flow equations yields valuable insight into the behavior of the NE-RFIM in 2D. The data collapses in a range of a factor of ten in the disorder and a factor of $10^4$ in the avalanche cutoff. The scaling is consistent with a critical disorder of zero and with a lower critical dimension of two.

Appendix A: Invariant Scaling Combinations

1. Power Law Form

As our invariant parameter combinations are unorthodox, we provide here a thorough derivation and a comparison to the usual power law ‘homogeneous’ variables seen at the usual hyperbolic fixed points. The invariant scaling combinations corresponding to traditional power law scaling may be simply derived from the flow equations in 3 and higher dimensions. We have

\[ \frac{dw}{d\ell} = \frac{1}{\nu}w \]
\[ \frac{ds}{d\ell} = -\frac{1}{\sigma\nu}s \]
\[ \frac{dh}{d\ell} = \frac{\beta\delta}{\nu}h \]

(A1)

Taking \((dw/d\ell)/(ds/d\ell)\) and integrating gives

\[ \int_{w_0}^{w^*} \frac{dw}{(1/\nu)w} = \int_{s_0}^{s^*} \frac{ds}{(-1/\sigma\nu)s} \]

(A2)

Performing the integral and working through the algebra

\[ \log w^* - \log w_0 = -\sigma(\log s^* - \log s_0) \]
\[ \Rightarrow \sigma \log(s_0) + \log w_0 = \sigma \log s^* + \log w^* \]
\[ \Rightarrow s_0^\sigma w_0 = \text{constant} \]

(A3)

where \((w^*, s^*)\) corresponds to the fixed point of the RG and is hence a constant. The invariant scaling combination in this instance is thus

\[ s^\sigma w \]

(A4)

which agrees with the results in 3 and higher dimensions [20]. Similarly for \(h\) we have

\[ \int_{w_0}^{w^*} \frac{dw}{(1/\nu)w} = \int_{h_0}^{h^*} \frac{dh}{(\beta\delta/\nu)h} \]

(A5)

Performing the integral and working through the algebra

\[ \beta\delta(\log w^* - \log w_0) = \log h^* - \log h_0 \]
\[ \Rightarrow \log h_0 - \beta\delta \log w_0 = \log h^* - \beta\delta \log w^* \]
\[ \Rightarrow h_0 w_0^{-\beta\delta} = \text{constant} \]

(A6)

The invariant scaling combination is hence

\[ h/w^{\beta\delta} \]

(A7)

which again agrees with the literature [20].

2. Transcritical Form

The flow equations using the transcritical form for the disorder are as follows

\[ \frac{dw}{d\ell} = w^2 + Bw^3 \]
\[ \frac{ds}{d\ell} = -d_fs - Cs\]
\[ \frac{dh}{d\ell} = \lambda h + Fhw \]

(A8)

As before, we take the integral of \(dw/d\ell\) over \(ds/d\ell\) and obtain

\[ \int_{s_0}^{s^*} (1/s) \, ds = \int_{w_0}^{w^*} \frac{-d_f - Cw}{w^2 + Bw^3} \, dw \]

(A9)

Solving for \(s_0\) we have

\[ s_0 = \left( B + \frac{1}{w_0} \right)^{-Bd_f+C} \exp \left( \frac{d_f}{w_0} \right) f(w^*, s^*) \]

(A10)

where \(f(w^*, s^*)\) denotes a function of \(w^*\) and \(s^*\) and is therefore constant. The invariant scaling combination in this case is then

\[ \frac{s}{\Sigma_{th}(w)} \]

(A11)

where

\[ \Sigma_{th}(w) = \left( B + \frac{1}{w} \right)^{-Bd_f+C} \exp \left( \frac{d_f}{w} \right) \]

(A12)

Likewise for \(h\) we obtain an invariant scaling combination

\[ \frac{h}{\eta_{th}(w)} \]

(A13)

where

\[ \eta_{th}(w) = \left( B + \frac{1}{w} \right)^{B\lambda h - F} \exp \left( -\frac{\lambda h}{w} \right) \]

(A14)

3. Alternative Transcritical Form

Applying our methods to the 2D equilibrium RFIM, we find that the fixed point is given by a pitchfork bifurcation corresponding to

\[ \frac{dw}{d\ell} = w^3 - Dw^5 \]

(A15)

In this instance, however, the behavior of the correlation length suggests an alternative choice for the normal form

\[ \frac{dw}{d\ell} = \frac{w^3}{1 + Dw^2} \]

(A16)
as discussed in [30]. This form, while retaining the pitchfork behavior, produces a well behaved correlation function that is also able to capture higher order corrections to scaling which we expect to become important further from the critical point. We may apply the same procedure in the non-equilibrium case, although the function for the correlation length here appears well behaved.

This yields an alternative form for the transcritical bifurcation given by

\[
\frac{dw}{d\ell} = \frac{w^2}{1 - Bw} \\
\frac{ds}{d\ell} = -df s - Csw \\
\frac{dh}{d\ell} = \lambda_h h + Fhw
\]

We can integrate the first equation to a final point \( \ell^* \), \( w^* \) to find the divergence of the correlation length \( \xi(w_0) = \exp(\ell^*) \):

\[
\int_{w_0}^{w^*} \frac{1}{w^2 - B/w} \, dw = \int_0^{\ell^*} d\ell
\]

\[
\ell^* = (-1/w - B \log w)|_0^r \\
= 1/w^0 + B \log w^0 - \text{constant}
\]

\[
\xi_{alt} = \exp(\ell^*) \propto w^B_0 \exp(1/w_0).
\]

As before, to determine \( \Sigma(w) \), we take the integral of \( dw/d\ell \) over \( ds/d\ell \) and obtain

\[
\int_{s_0}^{s^*} (1/s) \, ds = \int_{w_0}^{w^*} \frac{-df - Cw}{w^2/(1 - Bw)} \, dw
\]

Solving for \( s_0 \) we have

\[
s_0 = w_0^{d_B - C} \exp \left( \frac{df}{w_0} + BCw_0 \right) f(w^*, s^*)
\]

where \( f(w^*, s^*) \) denotes a function of \( w^* \) and \( s^* \) and is therefore constant. The invariant scaling combination in this case is then

\[
\frac{s}{\Sigma_{alt}(w)}
\]

where

\[
\Sigma_{alt}(w) = w^{Bd_B - C} \exp \left( \frac{df}{w} + BCw \right)
\]

Likewise for \( h \) we obtain an invariant scaling combination

\[
\frac{h}{\eta_{alt}(w)}
\]

where

\[
\eta_{alt}(w) = w^{-B\lambda_h + F} \exp \left( -\frac{\lambda_h}{w} - BFw \right)
\]

### 4. Pitchfork Form

The flow equations using a pitchfork form for the disorder are as follows

\[
\frac{dw}{d\ell} = w^3 + Bw^5 \\
\frac{ds}{d\ell} = -df s - Csw \\
\frac{dh}{d\ell} = \lambda_h h + Fhw
\]

As before, we take the integral of \( dw/d\ell \) over \( ds/d\ell \) and obtain

\[
\int_{s_0}^{s^*} (1/s) \, ds = \int_{w_0}^{w^*} \frac{-df - Cw}{w^3 + Bw^5} \, dw
\]

Solving for \( s_0 \) we have

\[
s_0 \sim w_0^{Bd_B} \left( 1 + Bw_0^2 \right)^{\frac{d_B}{2}} \sqrt{B} \exp \left( \frac{df}{2w_0^2} + \frac{C}{w_0} + \sqrt{BC} \arctan(\sqrt{B}w_0) \right)
\]

The invariant scaling combination in this case is then

\[
\frac{s}{\Sigma_{pl}(w)}
\]

where

\[
\Sigma_{pl}(w) = w^{Bd_B} \left( 1 + Bw^2 \right)^{\frac{d_B}{2}} \sqrt{B} \exp \left( \frac{df}{2w^2} + \frac{C}{w} + \sqrt{BC} \arctan(\sqrt{B}w) \right)
\]

Likewise for \( h \) we obtain an invariant scaling combination

\[
\frac{h}{\eta_{pl}(w)}
\]

where

\[
\eta_{pl}(w) = w^{-B\lambda_h} \left( 1 + Bw^2 \right)^{\frac{B\lambda_h}{2}} \sqrt{B} \exp \left( -\frac{\lambda_h}{2w^2} - \frac{F}{w} - \sqrt{BF} \arctan(\sqrt{B}w) \right)
\]

### Appendix B: Simulations

Experience simulating the RFIM on a square lattice has revealed a propensity for faceting in which the shape of the avalanche size distribution becomes dependent on properties of the lattice for small avalanche sizes. To mitigate this effect, we perform simulations on a periodic Voronoi lattice (Fig. 3) where, for each value of \( r \), we
consider 100 distinct lattices of size 1000x1000. Voronoi cells were chosen by generating random coordinates between 0 and 1 and constructing the cells with a 2D implementation of Voro++ \cite{38} provided by C. H. Rycroft. Examples of the avalanche behavior for different values of $r$ are shown in Figure 1.

We note that much larger simulations have been done on the square lattice, including a thorough analysis of results from a 131,072$^2$ lattice \cite{21,22}. In analysis of in-house simulations on a square lattice, however, we encountered long, unnaturally straight avalanche boundaries. We found these distortions strongly affected the shape of the size distribution for small disorders and served to effectively decreased the system size, a difficulty which became dramatically more pronounced as the disorder decreased. In addition to lattice dependent effects infecting the distributions for larger and larger avalanche sizes approaching the critical point, this effective reduction of system size encouraged the use of a Voronoi lattice.

From the simulations we extract two quantities of interest: the area weighted avalanche size distribution $A(s|r)$ \cite{39} and the change in magnetization of the sample with respect to the field $\frac{dM}{dr}(h|r)$. Alternatively, we may write these as $A(s|w)$ and $\frac{dM}{dh}(h|w)$ where $w$ is a function of $r$ as defined earlier.

Lattice effects are a major feature in the two-dimensional NE-RFIM. On the square lattice, the strong faceting effects due to the lattice distorted the avalanche size distribution, effectively giving a short-distance cut-off not of the lattice constant, but of the typical length $\xi_F$ of the straight, horizontal or vertical portions of the avalanche boundaries. On the random Voronoi lattices we simulate, the stochastic bond configurations introduce a randomness in the connectivity of the network, which we argue here may lead to an effective disorder that does not vanish even as $r_c \to 0$. One could envision off-lattice simulations or experiments that could bypass these effects. Here, instead, we shall briefly explore the faceting and intrinsic disorder, and speculate about strategies one might use to minimize their effects.

1. Faceting

The experimental systems to which we apply our avalanche model typically do not have an important underlying lattice anisotropy. The length scales of the domain wall pinning and avalanches are typically much larger than the atomic scale, and the materials are often amorphous or polycrystalline. We thus do not want an underlying crystalline lattice dominate the behavior on long length scales.

Often there are emergent symmetries at critical points. Lattice models (Ising, QCD) break rotational symmetry, but the emergent fluctuations on long length scales restore this symmetry – the symmetry of the fixed point is greater than that of the Hamiltonian. (The short-distance asymmetry is an irrelevant perturbation.) This is not always the case, as was vividly illustrated by diffusion-limited aggregation: simulations on a square lattice led to ‘dust balls’ of the form of giant crosses \cite{10,11}. There the anisotropy effects for small-scale simulations appeared unimportant; it was only when large simulations were visualized that the problem became apparent.

Are lattice effects relevant or irrelevant for our 2D NE-RFIM? In particular, simulations show that avalanche boundaries have long, straight segments in the horizontal and vertical directions. How do the typical lengths of these segments $\xi_F$ compare to the avalanche correlation length $\xi$ as we approach the critical point $r_c$? Can we modify the details of the model to minimize the effects of this faceting?

We can estimate the length scale $\xi_F$ as a function of disorder on the square lattice following Drossel and Dahmen \cite{18,42}. Consider a distribution $p(h|r)$ of random fields parameterized by disorder $r$. (For most simulations this is taken to be a normal distribution $p(h|r) = (1/\sqrt{2\pi r^2}) \exp(-h^2/2r^2)$.) On a square lattice, a flat initial horizontal or vertical interface can nucleate a pair of steps by flipping a spin at its edge; such a spin has only one neighbor up, so it must have a random field large enough that $-2J + H > 0$. The density of these nucleating sites at an external field $H$ is thus $p_1(H, r) = \int_{2J-H}^{\infty} p(h) dh$. Once nucleated, the steps can grow outward until they reach a pinning spin that will not flip until three of its neighbors are up. A spin will not flip with two neighbors up if $h < -H$, so these pinning sites happen with density $p_2(H, r) = \int_{-\infty}^{-H-h} p(h) dh$. By considering the possible two-dimensional static fronts that avoid the nucleating sites and ‘turn right’ only on the pinning sites \cite{13}, Drossel and Dahmen argue that for small disorder the interface must depin when $p_2 = \rho_3/(1 - \rho_1)$. They note that the length of the straight interface segments goes as $\xi_F \sim \rho_1^{-1}$.

If we use the traditional normal distribution, so $p_1(H, r) = (r/\sqrt{2\pi(2J-H)^2}) \exp(-(H-2J)^2/2r^2)$ and $p_2(H, r) = (r/\sqrt{2\pi H^2}) \exp(-H^2/2r^2)$ this implies $H_c \rightarrow r \to 0 \ 2(2 - \sqrt{2})J \approx 1.712 J$, and $(H_c - 2J)$. This tells us that the facet length scale for a normal distribution is

$$\xi_F \sim r \exp((H_c - 2J)^2/2r^2) = r \exp(2(3 - \sqrt{2})J^2/2r^2) \approx r \exp(0.343 J^2/2r^2).$$

(B1)

Under the hypothesis that $r_c = 0$, this suggests that faceting is a relevant perturbation, diverging faster as $r \to 0$ than our predicted correlation length divergence $\xi \sim (r/r_c)^B \exp(r_c/r)$ (Eq. [A20]). This is consistent with simulations which macroscopically show rough avalanche boundaries: just as for diffusion limited aggregation, the lattice anisotropy may be small far from the critical point and become dominant only for large systems close to critical. (An effect that grows faster as one approaches the critical point also dies faster as one departs from the crit-
ical region.) Presumably all the the avalanches would eventually become nearly rectangular at sufficiently large lattice sizes and low disorders. Even if \( r_e \) is not zero, it is definitely small for the square lattice, so \( \xi_F \) is large. Since scaling is not expected on lengths smaller than \( \xi_F \), the effective simulation size is reduced by a factor of \( (r/r_e)^2 \) (the facet length replacing the lattice cutoff), making it valuable to measure and reduce it.

It would be interesting to measure the distribution of segment lengths for avalanches in the 2D square-lattice NE-RFIM to test these predictions. One could also choose random field distributions \( p(r) \) that have fatter tails. If \( p(r) \sim \exp(-|H|/r) \) for large \( |H| \), the same argument predicts \( \xi_F \sim \exp(2J/3r) \). Comparing to the expected avalanche size divergence \( \xi \sim w^d \exp(1/w) = (r/r_e) \exp(r_e/r) \) (Eq. A20), and again assuming \( r_e = 0 \), the facet length could diverge more slowly than the avalanche size if the nonuniversal scale factor \( r_e > 2J/3 \).

Using a Cauchy distribution \( p[h] = (2r/\pi)/(r^2+h^2) \) with very fat tails would yield \( \xi_F \sim \sqrt{J/r} \), a much weaker divergence (smaller facets). One could also generalize Drossel and Dahmen’s results to other ordered lattices, to examine whether they are less susceptible to faceting.

One should be warned that many of these ideas were explored by Matthew Kuntz in his 1999 Ph.D. thesis [29]. He did not measure \( \xi_F \), but he did explore the behavior of the avalanche size distribution, both for different lattice structures and for a Cauchy distribution of random fields, with simulations up to size 45000\(^2\). He found that the disorder-dependent shape of the avalanche size distribution (the growing bump that prevented collapses like those in Fig. 1 of the main text) was remarkably invariant to lattice structure or disorder. Also, the intra-avalanche correlation function along the axes equaled the correlations along diagonals after only a few lattice spacings. Future work, thus, may uncover other explanations for the striking differences in behavior of the 2D NE-RFIM on regular and random lattices.

2. Intrinsic disorder from the Voronoi lattice

While our fits are consistent with \( r_e = 0 \), Fig. 4 in the main text is strongly suggestive of a simple scaling with \( r_e < 0 \). This is, of course, precisely what one would expect if the lower critical dimension is greater than two: at no disorder would an infinite system show system-spanning avalanches, and even in the limit of zero disorder we would not find broad distribution of avalanches sizes and scaling. This is thus a serious concern.

As we have focused on simulations all of the same size \( (10^6 \) spins), it is of course possible that the apparent \( r_e < 0 \) is a (surprisingly large) finite size effect, and would go away for larger systems. We suspect that this is not the case: instead, the negative disorder is due to our choice of a disordered bond network in the quest to remove faceting effects.

Even in the absence of random fields, our Voronoi lat-

tice simulations have disorder in the bond connectivity. On the left of Fig. 11, spins on different sites have different numbers of neighbors. At low disorder, a spin with eight neighbors will need at least four of the neighbors to flip, while a spin with four neighbors would need only two. For the equilibrium model, bond disorder is in a different universality class than random field disorder, because bond disorder in zero field preserves the up-down symmetry while random field disorder breaks that symmetry for each individual system, preserving it only for the ensemble. The NE-RFIM, however, has an external field growing from \( H = -\infty \); this external field history breaks the up-down symmetry, and indeed (as discussed above) the critical field is positive, not zero. Simulations [28] have shown, indeed, that the random-bond Ising model is in the same universality class as the random-field Ising model [35].

Fig. 4 in the main text suggests that the intrinsic randomness of our Voronoi lattice shifts \( r_e \) from zero to roughly \(-J/2 \) – corresponding to mean fluctuations of half of a bond. A spin at a growing front needs an external field to counteract the imbalance in the number of up and down neighbors; a spin with more neighbors will typically have a larger imbalance. The root-mean-square fluctuations in the number of bonds connecting a spin to its neighbors in a 2D Voronoi lattice with random sites is
1.334 [43], making the contribution of $-J/2$ in the effective random field entirely plausible. As mentioned in the text, one could test whether bond coordination randomness causes avalanches to remain finite in size by using fairly feasible simulations of $\sim 4 \times 10^8$ spins, if the challenge of building such a large Voronoi lattice could be surmounted.

Disordered lattices have also been explored for the NE-RFIM by Kurbah, Thongjaomayum and Shukla [24]. Site dilution of one sublattice of the triangular lattice allows them to explore average coordinations $Z$ continuously varying between three and six. As found in early work on the NE-RFIM on the Bethe lattice [44], they find a critical disorder at $Z_c = 4$, with no transition for $Z = 3$ and fitting to power-law scaling for $Z \geq 4$, with results consistent with the same critical exponents for all coordinations showing a transition. For $Z = 3$ and $Z = 6$, Kurbah et al. are subject to the same faceting problems concerns on the square lattice (and the triangular lattice [29]). For intermediate values, they have both rotational anisotropy and disorder. Later work by Shukla and Thongjaomayum [25] study the NE-RFIM on the diluted Bethe lattice, and find $Z_c = 3$ – lower than $Z_c = 4$ for the diluted triangular lattice, making the role of coordination in governing the behavior suspect. We would expect that the systems studied by Kurbah et al. will exhibit a negative critical random field strength $r_c < 0$ for all $3 < Z < 6$ – zero critical disorder but with contributions to the disorder both from the random field and from the random bonds.

Consider, for example, density fluctuations (Fig. 11). The sites far to the left and far to the right of the jump in density (red curve) have on average six neighbors (by Euler’s theorem), and thus have the same critical field at which the interface depins. However, the sites just to the left of the jump have typically more than six neighbors, and thus will demand a higher critical field in order to flip – just as if they had random fields pointing downward. It could be useful to explore Voronoi simulations whose lattices have been tailored to have reduced density fluctuations. These could be generated by adding Gaussian noise to regular lattices, or perhaps by generating lattices from jamming simulations. One could also increase the disorder by artificially correlating the positions of the spins, to see if $r_c$ becomes more negative – perhaps allowing simulations with $r = 0$ to be realized for relatively small lattices.

How can we argue that $r_c < 0$ is due to intrinsic disorder, and not partly also due to the lower critical dimension being higher than two? Our primary argument is the excellent (albeit non-power-law) scaling over a decade in disorder (Figs. 1-3 in the main text), and the excellent collapses found under the presumption that the RG flows have a lower critical dimension (transcritical bifurcation) in $d_u = 2$.
