We use a trial wavefunction to study the spin-1/2 Kondo effect of a helical metal on the surface of a 3-dimensional topological insulator. While the impurity spin is quenched by conduction electrons, the spin-spin correlation of the conduction electron and impurity is strongly anisotropic in both spin and spatial spaces. As a result of strong spin-orbit coupling, the out-of-plane component of the impurity spin is found to be fully screened by the orbital angular momentum of the conduction electrons.

On the surface of a 3-dimensional (3D) topological insulator, massless helical Dirac fermions emerge.\cite{1} Specific materials of 3D topological insulators have recently been studied and observed.\cite{2,3} Interesting properties of these helical Dirac fermions have become a focus of recent studies.\cite{4,5} In a helical metal, spins are coupled to momenta, so that magnetic properties are expected to be highly non-trivial. Theoretical study on this aspect, however, has so far been limited to the effect of a classical magnetic impurity.\cite{6}

The low temperature property of a quantum spin-1/2 magnetic impurity or an Anderson impurity in a conventional metal\cite{7} has been an interesting and important problem for decades in condensed matter physics. The problem has been studied by using the renormalization group\cite{8}, the Bethe ansatz\cite{9,10}, the 1/N-expansion\cite{11,12}, and the conformal field theory\cite{13}. The phenomenon is a well known Kondo effect, in which the impurity spin is completely screened by the conduction electrons. Because of the coupling between spins and momenta, the Kondo effect in a helical metal will be interesting to be examined. In this paper, we use a variational method to address this problem. We show that the correlation of the impurity spin and the conduction electron spin density is strongly anisotropic in both spatial and spin spaces, in contrast to the isotropic screening in a conventional metal. While the impurity spin is quenched at low temperatures, similar to the usual Kondo problem, the correlation between the impurity spin and the spin of the conduction electrons in the helical metal is significantly reduced. The reduction of the spin-spin correlation in the direction perpendicular to the surface can be shown explicitly to be compensated by the screening of the orbital angular momentum of the conduction electrons. The possible experimental consequences will be briefly discussed.

We consider a spin-1/2 magnetic impurity in a helical metal in a 2D x-y plane, described by the Hamiltonian,
\begin{equation}
H = H_c + H_{mix} + H_d
\end{equation}
where
\begin{align*}
H_c &= \sum_k c_k^\dagger \mathcal{H}_F(\mathbf{\sigma} \times \mathbf{k}) \cdot \mathbf{\hat{z}} - \mu c_k \\
H_{mix} &= \sum_k V_k c_k^\dagger d + h.c. \\
H_d &= (\epsilon_d - \mu)(n_{d\uparrow} + n_{d\downarrow}) + Um_{d\uparrow}m_{d\downarrow}.
\end{align*}

In the above equations, $c_k$ and $d$ are annihilation operators of the conduction electron with momentum $\mathbf{k}$ and of the $d$-electron at impurity site in the spinor representation, respectively. $\mathbf{\sigma}$ are the Pauli matrices, $\mu$ is the chemical potential, and $n_{d\sigma} = d_{\sigma}^\dagger d_{\sigma}$. $H_c$ describes a helical metal, and $H_d$ is a local impurity Hamiltonian with $\epsilon_d$ the impurity energy level and $U$ the Coulomb repulsion energy of the two $d$-electrons on the same impurity site. $H_{mix}$ is a hybridization term between the helical metal and the impurity state.

To start with, let us discuss the simple case $H_{mix} = 0$ first. In this limit, the helical metal and the impurity state are decoupled. The single electron eigen-energy and its corresponding eigenstate of the helical metal $H_c$ are...
The impurity site is singly occupied and has a local moment.

\[ \gamma_{k \pm} = \frac{1}{\sqrt{2}} (e^{\pm i \theta_k} c_{k \uparrow} \pm ie^{\pm i \theta_k} c_{k \downarrow}) \]  

(2)

with \( \theta_k \) the angle of the momentum \( k \) with respect to the \( x \)-axis that \( \tan \theta_k = k_y/k_x \) and “\( \pm \)” refer to upper and lower bands, respectively. For each single particle state, its spin lies in the plane and is perpendicular to the direction of its momentum. Note that such a spin-momentum relation has recently been reported in a spin- and angle-resolved photoemission spectroscopy (spin-ARPES) experiment [18]. The ground state of \( H_c \) is then given by

\[ |\Psi_0\rangle = \prod_{k \pm} \gamma_{k \pm}^{-1}|0\rangle, \]

where the product runs over all the states within the Fermi sea \( \Omega \). As for the impurity part, we shall consider an interesting case, where \( \epsilon_d < \mu < \epsilon_d + U \), so that the impurity site is singly occupied and has a local moment. The total energy of the system \( H_0 = H_c + H_d \) is then

\[ E_0 = \epsilon_d - \mu + \sum_{k s} \epsilon_{k s}, \]

where \( s = \pm \) is the band index and hereafter the sum of \( \{k s\} \) is always over the Fermi sea. In Fig. [1] we illustrate the electron dispersion and the spin of the Dirac fermion and the ground state of a helical metal, in the absence of the electron dispersion and the spin of the Dirac fermion.

To study the ground state of \( H \) in the presence of \( H_{mix} \), we will use a trial wavefunction approach. Such a trial wavefunction method was used to study the ground state of the Anderson impurity problem in the conventional metal [16,19] or in an antiferromagnet [20]. For simplicity, we consider here the large \( U \) limit, and exclude the double d-electron occupation at the impurity site. We expect the qualitative physics should apply to the case of finite but large \( U \). The trial wavefunction for the ground state is,

\[ |\Psi\rangle = (a_0 + \sum_{k s} a_{k s} d_{k s}^\dagger |\Psi_0\rangle \]  

(3)

where \( d_{k \pm} = \frac{1}{\sqrt{2}} (e^{\pm i \theta_k} d_{k \uparrow} \pm ie^{\pm i \theta_k} d_{k \downarrow}) \), and \( a_0 \) and \( a_{k s} \) are variational parameters. They are to be determined by optimizing the ground state energy. Note that by construction, the impurity state is either singly occupied or non-occupied.

The energy of \( H \) in the variational state \( |\Psi\rangle \) is given by

\[ E = \sum_{\{k s\}} (E_0 - \epsilon_{k s}) a_{k s}^2 + 2V_k a_0 a_{k s} + \epsilon_{k s} a_0^2 \]  

(4)

The variational method leads to the equations below,

\[ E - \sum_{\{k s\}} \epsilon_{k s} a_0 = \sum_{\{k s\}} V_k a_{k s} \]  

(5)

\[ E - E_0 + \epsilon_{k s} a_{k s} = V_k a_0 \]  

(6)

which may determine the binding energy \( \Delta_b = E_0 - E \) due to the hybridization,

\[ \epsilon_d - \mu - \Delta_b = \sum_{\{k s\}} \frac{|V_k|^2}{\epsilon_{k s} - \Delta_b}. \]  

(7)

If \( \Delta_b > 0 \), the hybridized state is stable against the decoupled state. To proceed further, we introduce an energy cutoff \( \Lambda \) for the helical metallic state in our analysis, and consider \( V_k = V/\Theta(\Lambda - hvF|k|) \), where \( \Theta(x) \) is a step function, which is 1 for \( x > 0 \) and 0 for \( x < 0 \). The low energy physics is expected to be insensitive to the cutoff \( \Lambda \). A natural energy cutoff for the helical metallic state in the topological insulator is the half of the bulk gap [3]. Eq. (7) enables us to determine the ground state energy \( E \) or the binding energy \( \Delta_b \) and the ground state wavefunction. The results are that the hybridization always leads to a binding \( \Delta_b > 0 \), and a magnetic screening of the conduction electrons to the impurity spin at any \( \mu \neq 0 \). At the Dirac point \( \mu = 0 \), the binding and screening only occur at the dimensionless hybridization strength \( \alpha = \frac{2\pi v^2}{\hbar vF} \) above a critical value. We will come back to this point later.

We shall first examine the magnetic properties of the system, which are most interesting. The central quantity we will examine is the correlation function of the impurity spin \( S_d = \frac{1}{2}d^\dagger \sigma d \) at the impurity site (set to be at the origin \( r = 0 \)) and the conduction electron spin density \( S_c = \frac{1}{2}\epsilon^\dagger(r)\sigma c(r) \) in the ground state, namely

\[ J_{uv}(r) \equiv \langle S_c^u(r)S_c^v(0) \rangle, \]  

(8)

where \( \langle Q \rangle \) is the ground state average of \( Q \), and \( u, v = x, y, z \) are the spin indices. If \( u \) and \( v \) are both on the \( x - y \) plane, we then have, by the rotational symmetry, \( J_{u'v'}(r') \equiv J_{uv}(r) \), if \( u' = R_z(\beta)u \), \( v' = R_z(\beta)v \), and \( r' = R_z(\beta)r \), with \( R_z(\beta) \) a rotational operator of angle \( \beta \) along the z-axis. \( J_{uv}(r) \) can be calculated by using the trial wavefunction in Eq. (3). Note that the variational parameter \( a_{k \pm} \) is independent of \( \theta_k \) since it can be expressed as \( V a_0/(\pm hvF|k| - \mu - \Delta_b) \) according to the Eq. (6). In terms of \( a_{k \pm} \), the diagonal components are found to be

\[ J_{zz}(r) = -\frac{1}{8} |B(r)|^2 + \frac{1}{8} |A(r)|^2 \]

\[ J_{xx}(r) = -\frac{1}{8} |B(r)|^2 - \frac{1}{8} Re(A^2(r)) \]

\[ J_{yy}(r) = -\frac{1}{8} |B(r)|^2 + \frac{1}{8} Re(A^2(r)) \]

where \( A(r) = \sum_{\{k s\}} e^{i k \cdot r + \theta_k} a_{k s} \) and \( B(r) = \sum_{\{k s\}} e^{i k \cdot r} a_{k s} \). \( J_{zz}(r) \) is rotational symmetric around the impurity site, while \( J_{xx}(r) \) and \( J_{yy}(r) \) are highly anisotropic in space. In Fig. [2] we show \( J_{zz}(r) \) and \( J_{yy}(x, 0) \). Note that \( J_{xx}(x, 0) = J_{zz}(x, 0) \) and their signs oscillate in space. A negative (positive) value means anti-parallel (parallel) correlation between the impurity
spin and the conduction electron spin density. Due to
the absence of the spin SU(2) symmetry, the off-diagonal
components are not zero in general and they are
\[
\begin{align*}
J_{xy}(r) &= J_{yx}(r) = -\frac{1}{8} \text{Im}(A(r)^2), \\
J_{xz}(r) &= -J_{zx}(r) = -\frac{1}{4} \text{Im}(B(r)A(r)), \\
J_{yz}(r) &= -J_{zy}(r) = -\frac{1}{4} \text{Re}(B(r)A(r)).
\end{align*}
\]

The spatial distributions of the spin correlations in 2D
are plotted in Fig. 3. As we can see, the magnitude of
\(J_{yy}(r)\) is larger at the space point \(r\) near the \(x\)-axis than
near the \(y\)-axis, and the magnitude of \(J_{xx}(r)\) is larger at
the space point \(r\) near the \(y\)-axis than near the \(x\)-axis.

The anisotropic spin correlation function implies that
the Kondo screening to a magnetic impurity in a helical
metal has more complex texture. In the strong spin-orbit
coupled system, the screening to the impurity spin may
be contributed from both the spins and orbital angular
momentum of the conduction electrons. In what follows,
we will show that in comparison with the Kondo effect
in a conventional metal, the spin-screening is largely
reduced, and the \(z\)-component of the impurity spin is
fully screened by the orbital angular momentum. Let us
first examine the correlation between the total spin of the
conduction electron, \(S_c = \int S_c(r) d^2r\) and the impurity
spin. We define
\[
I_u = \langle S_e^u S_d^u \rangle / \sum_{\{k_s\}} a^2_{k_s},
\]
with \(u = x, y, z\), where the denominator is the occupa-
tion number of the \(d\)-electron. \(I = \sum_u I_u\) is a measure
of spin-spin screening strength. \(I = 0\) if the conduction
electron and impurity state are decoupled. \(I = -3/4\) for
a spin-1/2 magnetic impurity in a conventional metal,
corresponding to a spin singlet of two spin-1/2. In the
present helical metal, when the Fermi level is at or below
the Dirac point, we find \(I_x = I_y = -\frac{3}{8}\) and \(I_z = 0\), there-
fore \(I = -\frac{1}{4}\), which is one third of the value of \(-3/4\) in
the usual Kondo problem. Note that although \(J_{zz}\) is non-zero
locally, its overall contribution to the spin-spin screening
is zero. The spin-screening comes from the in-plane
spin components. Since \(I\) is independent of any parameters
including the energy cutoff (the only requirement is \(\mu < 0\)), we expect that this is a general property of the
helical metal. When the Fermi level is above the Dirac
point, there is a deviation from the above result. For in-
stance, with the parameters \(\mu = 0.01\Lambda\) and \(\Delta_b = 0.005\Lambda\)
the deviation is about sixty percents of \(-1/4\). At \(\mu > 0\), the
upper Dirac cone is partially filled. The electron state
in the upper Dirac cone has spin orientation opposite to
the corresponding state in the lower Dirac cone, which
provides a stronger screening than induced by the lower

\[\text{Figure 2: (color online). Spatial Spin-spin correlation functions plotted in x-y plane. (a)} J_{xx}(x, y); (b) J_{yx}(x, y); (c) J_{yy}(x, y); (d) J_{yz}(x, y); (e) J_{yy}(x, y) \text{ or } J_{xy}(x, y); (f) J_{xy}(x, y) \text{ or } -J_{yx}(x, y). \text{ The parameters are the same as those in Fig. 2.}\]
band only. We remark that the difference between \( \mu < 0 \) and \( \mu > 0 \) is due to the particle-hole asymmetry in our model parameter with U large. If \( U + 2(\epsilon_d - \mu) = 0 \), we have particle-hole symmetry, and we expect corresponding symmetries for \( \mu < 0 \) and \( \mu > 0 \).

The conduction electron spin is not a good quantum number in a helical metal. To better understand the Kondo screening in the helical metal, we shall consider contribution from the orbital angular momentum. Because of the two dimensionality, only z-component of the orbital angular momentum can be considered here. The system is invariant with respect to a simultaneous rotation of both spin and space along the z-axis at the origin of the impurity site. Therefore, the z-component of the total angular momentum \( J_z = L_z + S_z^c + S_z^d \) commutes with the Hamiltonian \( H \) and is a good quantum number, where \( L_z \) is the total orbital angular momentum of the conduction electrons. Since the ground state preserves the particle-hole asymmetry in our model parameter with \( U \) large. If \( \mu > 0 \) and \( \mu < 0 \), we have particle-hole symmetry, and we expect corresponding symmetries for \( \mu < 0 \) and \( \mu > 0 \).

\[
\langle J^z S^z_d \rangle = \frac{\langle J^z S^z_d - S^z_c S^z_d - \langle S^z \rangle^2 \rangle}{\sum_{\{k\}} a_{ks}} = -\frac{1}{4}.
\]

Therefore, although spin-spin screening in the z-direction in the present Kondo problem vanishes, the orbital angular momentum \( L_z \) replaces the role of the conduction electron spin \( S_z^c \) to screen the impurity spin.

The spatial anisotropic correlations may be detected in spin resolved scanning tunneling spectroscopy (STM) experiments. The magnetic susceptibility is finite in this limit of small \( \alpha \), and \( \alpha \Lambda < \mu < \epsilon_d \), we have

\[
\Delta_b \approx \Lambda \exp \left[ \frac{-\epsilon_d - \epsilon_d - \alpha \Lambda}{\alpha |\mu|} \right], \mu < 0
\]

\[
\Delta_b \approx \frac{\epsilon_d^2}{\Lambda} \exp \left[ \frac{-\epsilon_d - \epsilon_d - \alpha \Lambda}{\alpha |\mu|} \right], \mu > 0.
\]

If the Fermi level is at the Dirac point, \( \mu = 0 \), \( \Delta_b \) has a positive value solution only if \( \alpha > \alpha_c = |\epsilon_d|/\Lambda \). In other words, for a given hybridization strength \( \alpha \), there is a critical value of the impurity \( d \)-level, below which there is no magnetic screening. This is due to the vanishing density of states at the Dirac point. This result is similar to the impurity problem in graphene. The binding energy as functions of the chemical potential \( \mu \) and the hybridization \( \alpha \) are plotted in Fig. 4.

\[
\Delta_b = \frac{\mu^2}{\alpha \Lambda} \exp \left[ \frac{-\mu - \epsilon_d - \alpha \Lambda}{\alpha |\mu|} \right], \mu < 0
\]

\[
\Delta_b = \Lambda \exp \left[ \frac{-\mu - \epsilon_d - \alpha \Lambda}{\alpha |\mu|} \right], \mu > 0.
\]

\( \Delta_b \) is asymmetric about the point \( \mu = 0 \). The solid curves in Fig. 4 are for \( \alpha = \alpha_c \) and \( \mu = 0 \) respectively. At \( \alpha > \alpha_c \), the hybridized state is always stable. At \( \alpha < \alpha_c \), the binding energy is strongly reduced around the Dirac point and vanishes at \( \mu = 0 \). As \( \alpha \rightarrow \alpha_c + 0^+ \), \( \Delta_b \approx |\alpha - \alpha_c| \Lambda \). This behavior is consistent with the result by using large-degeneracy method.

In summary, we have examined a spin-1/2 Anderson impurity in a 2D helical metal. The momentum-dependent spin orientation in the helical metal shows interesting magnetic properties. We have used a trial wavefunction method to study the system at the large Coulomb U limit. While the impurity spin is quenched by the conduction electrons, we find strong spin- and spatial-anisotropies in the correlations between the impurity spin and the conduction electron spin density. Because of the strong spin-orbit coupling, the orbital angular momentum also contributes significantly to the screening of the impurity spin. In particular, the out-of-plane component of the impurity spin is found to be fully screened by the orbital angular momentum of the conduction electrons. After our paper was submitted, there was a report on the experimental realization of the magnetic doping on the surface of the 3D topological insulator Bi2Se3, and a e-print by Zitko, who studied the essentially the same model as ours and mapped it onto a conventional Anderson pseudogap impurity model. He showed that the impurity spin is fully screened. Our trial wave-function method reported here is consistent with his result.

Finally we comment on the similarity and difference of the helical metal with the graphene. In terms of the eigen-energy problem, a helical metal is often considered to be a quarter of a graphene, where the pseudospin plays the similar role with the spin in helical metal. The graphene has a two-fold spin degeneracy and two-fold degeneracy associated with the two sublattices. Our results for the binding energy are similar to the graphene. However, because of the difference between the spin in the helical metal and the pseudospin in graphene, the mag-
netic properties of the two are different. If we consider only one of the two Dirac cones is coupled to the spin-1/2 impurity, the graphene behaves like a conventional metal.
