Abstract

\textbf{Background and Purpose:} Renal dysfunction is known to affect vasculature and lead to systemic arterial stiffness. It also independently increases the risk of cerebral small vessel disease (cSVD) and stroke. We aimed to examine the effect of renal dysfunction on cerebral hemodynamics and the burden of cSVD.

\textbf{Methods:} Of the 412 patients admitted to Seoul National University Hospital, between May 2015 and 2019, with lacunar infarction and no major intracranial arterial stenosis observed on magnetic resonance angiography, we included 283 patients who had undergone a transcranial Doppler (TCD) ultrasound after 72 h of stroke onset. The patients were divided into renal dysfunction (estimated glomerular filtration rate [eGFR] <60 mL/min/1.73 m\textsuperscript{2} at admission) and control (eGFR ≥60 mL/min/1.73 m\textsuperscript{2}) groups. We investigated the correlations between renal function, the pulsatility index (PI), and the total MRI burden of cSVD. Furthermore, multivariate analysis was performed to assess the association between renal dysfunction and the PI of the middle cerebral artery (MCA) measured through TCD ultrasound.

\textbf{Results:} Among the total patients, 74 (26.1\%) had renal dysfunction (eGFR <60 mL/min/1.73 m\textsuperscript{2} at admission). Patients with renal dysfunction were significantly older, showed higher pulse pressure, and had a higher prevalence of hypertension, diabetes mellitus, and coronary artery disease. Renal dysfunction was significantly associated with higher distal cerebrovascular flow resistance (median PI 1.12, interquartile range [IQR]: 0.85–1.57 vs. controls 0.84, IQR: 0.54–1.22; \textit{p}< 0.001). Also, patients with renal dysfunction had a significantly higher total MRI burden of cSVD (median cSVD score 2, IQR: 1–3 vs. controls median score 1, IQR: 0–2; \textit{p}< 0.001). There was an inverse proportional relationship between the PI and eGFR. Finally, multivariate analysis showed renal dysfunction (adjusted odds ratio: 4.516, 95\% confidence interval: 1.051–20.292) and older age (adjusted odds ratio: 1.076, 95\% confidence interval: 1.038–1.114) as independent predictors of a high PI.

\textbf{Conclusions:} Renal dysfunction is independently associated with a high PI of MCA. Renal dysfunction leads to systemic arterial stiffness including stiffness in cerebral arteries, thus increasing the burden of cSVD. Therefore, noninvasive screening for high PI by TCD in kidney failure patients might be helpful.
Introduction

Poor renal function is known to affect the systemic vasculature and vascular remodeling, eventually leading to systemic arterial stiffness [1, 2]. Arterial stiffening generally results from oxidative stress and chronic inflammation of the arterial wall, involving a variety of pathological factors of kidney disease, including uremic toxins [3]. Additionally, renal dysfunction increases the burden of cerebral small vessel disease (cSVD) and the risk of stroke [4, 5]. The underlying causes of the progression of cSVD are poorly understood; however, the persistent pulsatile stress from systemic arterial stiffness has been suggested as a possible cause [6].

Transcranial Doppler (TCD) ultrasound is a noninvasive investigation used to obtain cerebral hemodynamic data, including Gosling’s pulsatility index (PI). PI indicates the degree of downstream vascular resistance to flow. Aggravation of arterial stiffness decreases the damping of the vascular flow and increases PI of the cerebral blood flow [7]. Furthermore, it has been considered that increased PI of the middle cerebral artery (MCA) could be associated with cerebral arteriosclerosis, progression of white matter hyperintensities (WMHs), and cerebral atrophy [8, 9].

Therefore, we hypothesized that renal dysfunction affects systemic vasculature including cerebral arteries and is associated with high PI of MCA. To determine the effect of renal dysfunction on cerebral hemodynamics and burden of cSVD, this study aimed to analyze PI by kidney function. Moreover, we investigated the impacts of renal dysfunction on the total burden of cSVD.

Materials and Methods

Participants

In this retrospective study, we reviewed consecutive patients with acute ischemic stroke who had been admitted to Seoul National University Hospital between May 2015 and 2019. We identified 412 patients with lacunar infarcts without any major intracranial arterial stenosis or occlusion on magnetic resonance angiography. We defined lacunar infarction as a small infarct (<20 mm on diffusion-weighted image) in the territory of the perforating artery. Among these patients, 393 had undergone a TCD examination. Patients who had undergone TCD examinations ≤72 h after ischemic stroke were excluded because of potential hemodynamic changes during the acute phase of ischemic stroke. We also excluded patients with atrial fibrillation or poor temporal isonation windows. Patients with internal carotid artery stenosis above 50% by The North American Symptomatic Carotid Endarterectomy Trial criteria were also excluded. In effect, the final study population was 283. The study was approved by the Seoul National University Hospital Institutional Review Board. Informed consent was waived by the Institutional Review Board due to the retrospective nature of this study.

Measurements

We undertook a retrospective chart review to collect patient demographic and clinical data. TCD examinations were performed by experienced ultrasonographers at the Seoul National University Hospital. Both MCAs were examined at multiple depths using a transtemporal window. The PI was calculated using the following formula:

$$PI = \frac{\text{peak systolic velocity} - \text{end diastolic velocity}}{\text{mean flow velocity}}$$

We defined the PI of the bilateral MCAs as the mean of all measured PI values in both MCAs. Because the normal range of PI is 0.6–1.1, we defined high PI as above 1.1 [10].

Blood pressure and heart rate were measured immediately before the TCD examination using an automated blood pressure device. All evaluations were performed twice while the patient was sitting in a chair. Pulse pressure was calculated by subtracting the average diastolic blood pressure from the average systolic blood pressure. The heart rate of each patient was based on the average of the 2 measurements.

An experienced neurologist and a radiologist separately reviewed the results of brain MRI and were blinded to the clinical information and TCD findings. The definition of the standard criteria for markers for cSVD is based on international consensus [11]. We used the total cSVD score, composed of all 4 imaging markers of cSVD, to evaluate the total cSVD burden based on a recently developed scoring system [12–14]. One point was assigned for the presence of each marker: WMHs, with either irregular periventricular hyperintensities extending into the deep white matter (Fazekas score 3) and/or confluent deep WMHs (Fazekas score 2 or 3); a lacuna of <20 mm in diameter, located in the internal or external capsule, basal ganglia, thalamus, or brain stem and not competed with the clinical symptoms; a deep cerebral microbleed located in the internal or external capsule, basal ganglia, or thalamus; and enlarged perivascular space with a scale of 2 or 3 in the basal ganglia, according to a 3-category ordinal scale (0–10, 10–25, and >25), in the hemisphere with the highest number of extensive perivascular spaces. Scores ranged from 0 to 4 and described the severity of the total cSVD burden.

Statistical Analysis

Means and medians were used as measurements of central tendencies as appropriate, with corresponding standard deviations and interquartile ranges, respectively. Comparisons between groups according to renal function were performed using Fisher’s exact test for proportions. Continuous variables were analyzed using the Wilcoxon rank-sum test. The difference in total MRI burden of cSVD score and each feature of cSVD between renal dysfunction and control groups was analyzed. The correlation between the PI value and the total MRI burden of cSVD score was explored by linear regression analysis. For factors predicting the higher total MRI cSVD score, multiple linear regression was performed. We investigated the relationship between eGFR distribution and the PI to divide the eGFR into 5 categories. The eGFR levels were selected based on a chronic kidney disease classification in accordance with the National Kidney Foundation-Kidney Disease Outcomes Quality Initiative: eGFR ≥90 mL/min per 1.73 m², eGFR 60–89 mL/min per 1.73 m², eGFR 30–59 mL/min per 1.73 m², eGFR 15–29 mL/min per 1.73 m², and eGFR 0–14 mL/min per 1.73 m².
<15 mL/min per 1.73 m². In this study, an eGFR ≥60 mL/min per 1.73 m² was classified as no renal dysfunction, and we selected patients with this eGFR as controls [15]. The diagnostic criteria of CKD require longitudinal eGFR data from at least 3 months, and because follow-up eGFRs were not available for all patients, we analyzed the data according to eGFR levels at admission rather than CKD stages. Finally, with the high PI (>1.1) as the dependent variable, multivariate models were constructed to examine whether renal dysfunction independently increased the PI. Statistical analysis was performed using IBM SPSS version 25 (IBM Corp., Armonk, NY, USA). A 2-sided p value of <0.05 was considered statistically significant.

**Results**

**Baseline Characteristics of the Patients according to Kidney Function**

Of the 412 patients with acute lacunar infarction, 283 had undergone a TCD examination at least 72 h after stroke onset. The average time taken from the stroke onset to the TCD was 6,830.02 ± 2,129.52 min. Of these, 74 (26.1%) had renal dysfunction (eGFR <60 mL/min/1.73 m² at admission). Table 1 shows patient demographics, vascular comorbidities, and laboratory findings. Among the total patients, 67.8% were male. The mean ages of those without and those with renal dysfunction were 65.43 ± 9.66 and 71.82 ± 10.96 years, respectively. The patients with renal dysfunction were significantly older, showed higher level of pulse pressure (84.15 ± 23.09 mm Hg vs. control group 70.03 ± 19.87 mm Hg, p < 0.001), and had a higher prevalence of hypertension (87.8% vs. control group 73.2%, p < 0.001), diabetes mellitus (59.5% vs. control group 35.9%, p < 0.001), and coronary artery disease (23.0% vs. control group 5.7%, p < 0.001).
Renal Dysfunction and Cerebral Hemodynamics

0.001) than the control group. However, hematocrit (37.67 ± 5.47% vs. control 41.51 ± 4.81%, p < 0.001) and platelet count (208.63 ± 68.11 × 10^3/μL vs. control 227.95 ± 56.42 × 10^3/μL, p = 0.018) were significantly lower in the renal dysfunction group. Renal dysfunction was significantly associated with higher arterial stiffness (median PI 1.12, interquartile range [IQR]: 0.85–1.57 vs. controls median PI 0.84, IQR: 0.54–1.22; p < 0.001) of MCA. Furthermore, a proportional relationship was found between the degree of renal dysfunction and PI (shown in Fig. 1).

**The Total Burden of cSVD according to Renal Function**

The total MRI cSVD score was calculated using a previously explained 4-point scale. Each 1 point was assigned for the presence of each of the following: the presence of 1 or more lacunes, presence of cerebral microbleeds, moderate to severe basal ganglia PVSs, and WMHs. Patients with renal dysfunction (eGFR <60 mL/min per 1.73 m^2) had a significantly higher cSVD burden than the control group (renal dysfunction group median: 2, IQR: 1–3; control group median: 1, IQR: 0–2, p < 0.001). All kinds of cSVDs, lacunes, cerebral microbleeds, extensive perivascular spaces, and WMHs, were observed significantly more frequently in patients with renal dysfunction. In the linear regression analysis, the total MRI burden of cSVD was significantly associated with MCA PI (p < 0.001, see Table 2). Besides, in the multiple linear regression analysis, old age (β 0.601, standard error [SE] 0.005, p < 0.001) and renal dysfunction (β 0.226, SE 0.114, p < 0.001) were significantly correlated with total MRI cSVD score (Table 3).

### Factors Associated with High Intracranial Vascular Resistance

A stepwise multivariate linear regression analysis was performed to identify independent predictors of the high PI (>1.1). Risk factors known to affect arterial stiffness, such as older age, hypertension, diabetes mellitus, dyslipidemia, coronary artery disease, previous history of stroke or transient ischemic attack, smoking, and pulse pressure, were included. We also included hematocrit as a variable considering that blood viscosity may affect the result of TCD. Renal dysfunction (adjusted odds ratio [aOR]: 4.516, 95% confidence interval [CI]: 1.051–20.292) and older age (aOR: 1.076, 95% CI: 1.038–1.114) were independent predictors of a high PI in the multivariate model (Table 4).

### Discussion

Renal dysfunction is known to affect systemic vasculature and lead to arterial stiffness caused by various uremic toxins. Earlier studies showed a gradual decline in renal excretion causing an increase in serum phosphates. Increased phosphate levels may induce vascular calcification directly through activation of proinflammatory molecules that are signaled in vascular smooth muscle cells [16]. Uric acid, another vascular toxin, is increased in patients with renal dysfunction. Uric acid decreases nitric oxide production by impeding the activity of endothelial nitric oxide synthase, which facilitates the proliferation of vascular smooth muscle cells [17]. Lastly, hypertriglyceridemia is frequently found in patients with renal dysfunction [18]. This condition can trigger oxidative stress, vascular inflammation, foam cell formation, and endothelial dysfunction [19].

Previous studies have suggested that renal dysfunction independently predicts the presence of cSVD [5].
Central arterial stiffness, such as aortic stiffening, transmits potentially harmful pulsatile energy to distal vessels [20]. Increased transmission of this energy into peripheral arteries causes reactive changes in distal vascular resistance to flow as well. If this is maintained over a long duration, it will lead to remodeling of the vessel wall composition and permanent changes in the distal vasculature [21]. Therefore, this mechanism is considered to have the pathophysiological potential to progression of cSVD.

The results of our study support those from previous studies that renal dysfunction causes stiffness of systemic vasculature and leads to the progression of cSVD. Furthermore, we demonstrated an inverse proportional relationship between the aggravation of renal dysfunction and the increase of PI. Thus, our results show that the progression of cSVD might be due to aggravation of systemic and cerebral arterial stiffness caused by renal dysfunction. Because the presence of cSVD is known to be associated with a higher risk of stroke and its unfavorable outcomes, these data provide evidence for the need to as-

### Table 2. MRI feature and total burden of cSVD according to renal function

| MRI feature                        | All, n (%) or median (IQR) (N = 283) | Renal function | p value |
|------------------------------------|--------------------------------------|----------------|---------|

sess the risk of ischemic stroke using TCD in patients with kidney failure and for early intervention addressing risk factors for ischemic stroke.

A strength of this study is that the PI was accurately evaluated by excluding any stenosis or occlusion in the cerebral arteries. Considering hemodynamic changes that occur in the acute stroke phase, we did not include TCD data that had been obtained <72 h from symptom onset time. In addition to those risk factors related to arterial stiffness, we adjusted for hematocrit, which may affect the results of TCD. Furthermore, we showed a consistent trend that the PI of MCA is inversely proportional to the eGFR measured at admission. This has not been reported in any previous study.

This study had some limitations. First, it was a single-center, retrospectively designed study, and the sample size was relatively small. Second, we did not assess all medical conditions such as cerebral edema which may influence the PI. However, we only included lacunar stroke patients, and no patient had a craniectomy. Therefore, it is assumed that the effect of cerebral edema was insignificant in this study. Last, we defined the renal dysfunction from a single examination performed at admission. A follow-up evaluation of renal function was not performed in all patients. Renal dysfunction might be overdiagnosed due to concomitant medical conditions such as dehydration related to acute stroke. Also, data were cross-sectional, and we were not able to address longitudinal relationships between the aggravation of renal dysfunction and changes in cerebral hemodynamics. Further, large-scale studies considering these factors will be needed to validate our results.

**Conclusion**

Renal dysfunction is known to affect the vasculature and eventually leads to systemic arterial stiffness. Pulsatile stress from arterial stiffness is known to be associated with the progression of cSVD. We demonstrated that renal dysfunction is independently associated with a high PI and correlates with the total burden of cSVD. Noninvasive screening for cSVD by TCD in kidney failure patients might be helpful.

**Statement of Ethics**

The study was approved by the Seoul National University Hospital Institutional Review Board (IRB No. 1009-062-332) and was conducted in accordance with ethical standards stated in the Declaration of Helsinki, 1983. Informed consent was waived by the Institutional Review Board due to the retrospective nature of this study.

**Conflict of Interest Statement**

The authors have no conflicts of interest to declare.
