Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

ABSTRACT

Antiviral agents with different mechanisms of action could induce synergistic effects against SARS-CoV-2 infection. Some reports suggest the therapeutic potential of the heme oxygenase-1 (HO-1) enzyme against virus infection. Given that hemin is a natural inducer of the HO-1 gene, the aim of this study was to develop an \textit{in vitro} assay to analyze the antiviral potency of hemin against SARS-CoV-2 infection. A SARS-CoV-2 infectivity assay was conducted in Vero-E6 and Calu-3 epithelial cell lines. The antiviral effect of hemin, and chloroquine as a control, against SARS-CoV-2 virus infection was quantified by RT-qPCR using specific oligonucleotides for the N gene. Chloroquine induced a marked reduction of viral genome copies in kidney epithelial Vero-E6 cells but not in lung cancer Calu-3 cells. Hemin administration to the culture medium induced a high induction in the expression of the HO-1 gene that was stronger in Vero-E6 macaque-derived cells than in the human Calu-3 cell line. However, hemin treatment did not modify SARS-CoV-2 replication, as measured by viral genome quantification 48 h post-infection for Vero-E6 and 72 h post-infection for the Calu-3 lineages. In conclusion, although exposure to hemin induced strong HO-1 up-regulation, this effect was unable to inhibit or delay the progression of SARS-CoV-2 infection in two epithelial cell lines susceptible to infection.

1. Introduction

The severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) has spread globally causing a pandemic of respiratory illness, the so-called coronavirus disease 2019 (COVID-19). Drugs against COVID-19 are urgently needed and promising antiviral agents that delay the progression of SARS-CoV-2 infection are currently being tested in clinical trials [1]. Antivirals could have different mechanisms of action and combined administration of different agents could induce synergistic effects. Some reports have shown an inverse correlation between the induction of the catabolic enzyme heme oxygenase-1 (HO-1, EC: 1.14.14.18) and pathogen infections [2–4]. A dose response anti-viral effect to hemin treatment has been reported in Ebola-infected HeLa and HFF1 cells [5], MARC-145 cells infected with porcine reproductive and respiratory syndrome virus [6], as well as in A301 and Jurkat cells [7] or human monocytes [8] infected with human immunodeficiency virus (HIV). Indeed, it has been reported that cobalt protoporphyrin (CoPP), a potent HO-1 inducer similar to hemin, inhibits influenza A virus replication through HO-1 interaction with IRF3 and subsequent induction of the expression of IFNα/β [9]. Of note, the antiviral effect of HO-1, mediated by CoPP, was able to control numerous other viral infections, such as those produced by human respiratory syncytial virus, Ebola virus, and HIV by inhibiting virus replication [10–12].

Given that hemin is a natural inducer of the HO-1 gene, and an approved drug for the treatment of acute intermittent porphyria [13] the aim of this study was to develop an \textit{in vitro} assay to analyze the antiviral potency of hemin treatment against SARS-CoV-2 (Graphical abstract and Fig. 1A).

Fig. 1. Effects of hemin administration on rate limiting enzymes of heme synthesis and catabolism. A) Regulation of heme synthesis and potential antiviral effect of hemin administration. The first and rate limiting step in heme synthesis is the conversion of glycine and succinyl-coenzyme A to form δ-aminolevulinic acid (ALA), catalyzed by ALA synthase-1 (ALAS1). Heme oxygenase-1 (HO-1) is the inducible isoform of HO responsible for the oxidative cleavage of heme groups to yield carbon monoxide (CO) and biliverdin, which is subsequently reduced to bilirubin by the cytosolic biliverdin reductase enzyme. CO is a strong vasodilatory, anti-inflammatory and immunomodulatory agent and both biliverdin reductase B and bilirubin are efficient scavengers of Reactive Oxygen Species (ROS) and reduce the formation of peroxidation products. Fold-change expression of HO-1 in B) Vero-E6 and C) Calu-3 cell lines was measured after exposure to 64.4 µM of hemin. Immunoblot analyses of HO-1 protein levels in D) Vero-E6 and E) Calu-3 cell lines treated with two hemin concentrations (21.5 µM and 64.4 µM) for 48 h. F) Fold change of ALAS1 expression after hemin exposure. Results were plotted as mean ± SD from three experiments. *** p < 0.001 vs untreated control condition.
2. Material and methods

SARS-CoV-2 infectivity assay in cultured cells. SARS-CoV-2 susceptible Vero-E6 (isolated from kidney epithelial cells extracted from an African green monkey, Chlorocebus sp., ATCC® CRL-1586™) and Calu-3 (human lung cancer epithelial cell, ATCC® HTB-55™) cell lines were used. Vero subtype E6 cells have shown to be infected better by SARS-CoV-2 than regular Vero cells [14]. Calu-3 cells have been used to analyze the effect of several antiviral compounds against SARS-CoV-2 [15,16]. The fact that Calu-3 cells derive from human lung epithelium, a tissue preferentially infected by SARS-CoV-2, as well as the fact that these cells maintain a normal type I interferon response, make them a very good alternative infected by SARS-CoV-2, as well as the fact that these cells were obtained. As a first step, the virus was grown in Vero-E6 cells; confluent monolayers of Vero-E6 and Calu-3 cells were infected with a low multiplicity of infection (MOI: 0.05; MOI(NAVARRA-2473):0.1) in the presence or absence of hemin (64.4 µM) (heme arginate, Normosang®; Recordati) or chloroquine diphasate salt (10 µM, C6628 Sigma-Aldrich). In a pre-treatment approach, drugs were administered 24 h before infection with SARS-CoV-2. The medium was refreshed every 24 h and supernatants were collected for reverse transcription PCR (RT-qPCR) assays and titrated as described above. For the analysis of SARS-CoV-2 genome. No toxicity was observed in Vero-E6 and Calu-3 cells but not in Calu-3 cells, as previously reported [18]. These data suggest that the induction of HO-1 is the consequence of a regulatory mechanism activated to eliminate the excess of hemin accumulating inside the cells (Fig. 1A).

Although hemin administration induced a strong up-regulation of the HO-1 gene in all cell lines, it was not able to inhibit SARS-CoV-2 infection and replication, as measured by viral genome quantification 48 h post-infection for Vero-E6 and 72 h post-infection for Calu-3 cells (Fig. 2A). These data rule out any potential protective effect of hemin catabolism products against the infection and the replication of the SARS-CoV-2 genome. No toxicity was observed in Vero-E6 and Calu-3 cells incubated with 64.4 µM of hemin, which was measured as described in Methods (data not shown).

As a control in our study, we verified that the administration of 10 µM of chloroquine significantly inhibited viral replication in Vero-E6 cells but not in Calu-3 cells, as previously reported [18]. These data confirm that the study design was valid to quantify viral infectivity of the SARS-CoV-2 (Fig. 2B).

4. Discussion

The effect of human hemin (heme arginate, Normosang® in Europe and crystalized hemin, Panhematin® in the US, both from Recordati) against SARS-CoV-2 infection was assayed in in vitro assays and compared to chloroquine, whose clinical efficacy is being studied [19]. Various reports showed anti-inflammatory and anti-thrombotic effects of chloroquine therapy that could improve the treatment of COVID-19 patients. Furthermore, it has been described that hydroxychloroquine efficiently blocked viral entry and reduced SARS-CoV-2 genomes in Vero-E6 cells [20,21]. Thus, chloroquine was used as a positive control to evaluate changes of SARS-CoV-2 genome.

Different reports showed that increased levels of HO-1 serve as a cellular defensive response, because the biliverdin and carbon monoxide product length: 224 bp); Results are expressed according to the formula \( \frac{2^{\Delta \Delta Ct(Actin)}}{2^{\Delta \Delta Ct(gene)}} \). To test toxicity, Vero-E6 and Calu-3 cells were incubated with hemin at 64.4 µM or chloroquine at 10 µM during 72 h and 96 h, respectively, and cell viability was analyzed using a commercial kit (CellTiter-Glo assay, Promega).

Procedures involving SARS-CoV-2 were performed in a BSL3 (P3 Security) laboratory at CIMA-Universidad de Navarra with the authorization and permissions from the Regional Government of Navarra, Spain.

Statistical analyses were performed using GraphPad Prism 9 (GraphPad Software). Before statistical analysis, data were transformed using the formula \( (1 + x) \) to normalize the variances. Data were analyzed using one-way ANOVA, and pairwise comparisons were made using Bonferroni’s multiple comparison tests. P < 0.05 was used to indicate statistically significant differences.

3. Results

As expected, administration of hemin (64.4 µM) to the culture medium induced a marked increase in the expression of the HO-1 gene (Fig. 1B-C), the inducible isoform of the HO that mediates the regulatory step in heme catabolism. HO-1 up-regulation was stronger in Vero-E6 than in Calu-3 cells and the induction was maintained throughout the exposure period in both cell lines. HO-1 protein levels, as detected by immunoblot, were also strongly induced by hemin (Fig. 1D-E). In fact, HO-1 expression increased with hemin concentrations from 21.5 to 64.4 µM, which was the dose chosen for the anti-viral studies.

The expression of the ALAS1 gene, the rate-limiting enzyme in the heme synthesis pathway was significantly reduced by the presence of the final product of this pathway, i.e. hemin (Fig. 1F). Given that down-regulation of the human ALAS1 gene has been previously documented in the human hepatoma HuH-7 cell line after hemin exposure [17], reduced ALAS1 mRNA levels confirmed efficient hemin uptake in the two cell lines used in the in vitro study. Overall, these data suggest that the induction of HO-1 is the consequence of a regulatory mechanism activated to eliminate the excess of hemin accumulating inside the cells. The effect of human hemin (heme arginate, Normosang® in Europe and crystalized hemin, Panhematin® in the US, both from Recordati) against SARS-CoV-2 infection was assayed in in vitro assays and compared to chloroquine, whose clinical efficacy is being studied [19]. Various reports showed anti-inflammatory and anti-thrombotic effects of chloroquine therapy that could improve the treatment of COVID-19 patients. Furthermore, it has been described that hydroxychloroquine efficiently blocked viral entry and reduced SARS-CoV-2 genomes in Vero-E6 cells [20,21]. Thus, chloroquine was used as a positive control to evaluate changes of SARS-CoV-2 genome.
CO), products released in the HO-1 reaction, have immunomodulatory, anti-inflammatory and antiapoptotic properties [2–8]. Huang and collaborators also suggested an important role for HO-1 induction in primary human monocyte-derived macrophages as an intracellular mediator in restricting Ebola [5] and Zika virus [22] replication. Since most studies testing anti-viral effects of hemin have reported an EC$_{50}$ ≈ 30 μM, we reasoned that a concentration of 64.4 μM should be adequate to test SARS-CoV-2 inhibition [5]. In addition, hemin is nephrotoxic at high doses and its continued use can generate iron overload and chronic inflammatory hepatic disease [23]. Thus, based on current knowledge of hemin pharmacology in humans, we used a dose of 64.4 μM, which is similar to the concentration of 64.4 μM used to treat acute intermittent porphyria attacks [13].

However, in the present study, no direct anti-SARS-CoV-2 effect was observed after the exposure of epithelial cells to hemin. The induction of HO-1 gene was stronger in Vero-E6 macaque-derived cells than in the human Calu-3 cell line, but this strong effect did not modify SARS-CoV-2 infection and replication. Although the number of tested cell lines is limited, we believe that similar results would be expected in other cell lines.

Nevertheless, we cannot rule out that hemin and/or CO could have an effect in vivo associated to the suppression/reduction of the inflammatory signaling pathways and production of pro-inflammatory cytokines, such as TNF-α, IL-6, and IFN-γ, or the inhibition of antigen presentation and subsequent immune activation, as reported for chloroquine.

5. Conclusion

Although exposure to hemin induced a strong expression of the HO-1 gene in two epithelial cell lines susceptible to SARS-CoV-2 infection, this response was not able to inhibit or delay SARS-CoV-2 infection and replication.
