Two new species of *Neomachilellus* Wygodzinsky (Meinertellidae, Microcoryphia) from the state of Amazonas, Brazil

Pedro Wygodzinsky (*)

Abstract

Two new species of Microcoryphia, *Neomachilellus adisi* and *N. scandens*, occurring in the inundation forests near Manaus and collected in tree-traps, are described and compared to other species of the genus.

The present paper contains the descriptions of two new species of the large, mainly neotropical machilid genus *Neomachilellus* Wygodzinsky, with the purpose of making their names available for ecosystem analyses now being carried out by Adis (1977) in the inundation forests near Manaus, between December 1975 and May 1977. The species here described belong to a group of the genus so far known only from southern Brazil. The apparent absence near Manaus of the northern South American genus *Meinertellus* Silvestri is notable.

*Neomachilellus adisi*, sp. n.
(Figures 1A, 2, 3)

Maximum observed body length 12 mm; maximum length or antennae 18 mm, of terminal filament 14 mm. Color of body light yellow; hypodermal pigment on head, mouthparts, antennae and legs. Color pattern formed by scales, unknown.

Head with 1+1 pigment spots between ocelli and 1+1 spots behind ocelli (figs. 1A, 3D). Color pattern of eyes (fig. 2A) consisting of three dark, curved stripes, their curvature parallel to that of anterior margin of eyes; uppermost dark stripe wider than the two others. Eyes approximately as long as wide, their line of contact equal to five sixth of their length. Ocelli (figs. 1A, 3D) only slightly shorter than anterior border of eyes, narrowly sole-shaped. Head capsule without secondary sexual characters. Antennae longer than body.

Scapus with pigment arranged as shown in figure 1A, characterized by elongate parallel-sided marking on outer surface. Flagellum light brown, with intermediate jointlets slightly but distinctly darker than chains (fig. 3E). Pigmentation of mandibles as shown in figure 2C. Maxillary palpi as shown in figures 2E, 3A, their pigment pattern characterized by narrow longitudinal dark mark on second article with field of short, semierect hairs (fig. 1J); remaining articles without special features; seventh as long as penultimate. Labial palpi narrowly bordered with pigment along anterior surface (figs. 2B, 3F). Terminal article of labial palp strongly widened in both sexes, almost twice as wide as long in male.

Pigmentation of legs as shown in figures 2F, G; 3B, C, characterized by elongate narrow marking on tibiae of all legs, although in some cases less developed on hind legs (fig. 3C). Femora and tibiae without spine-like setae; although some present on tarsi. Underside of hind tibiae with very numerous short, simple setae (fig. 2I).

Stylets of ninth abdominal segment of male as long as coxite (fig. 2H), in female three fourths as long as coxite. Distal spine of stylet V one half as long as stylet (fig. 3G), distal spine of stylet IX one fourth as long as stylet (fig. 2H).

Apical portion of penis as illustrated (fig. 2K). Ovipositor attaining level of terminal spine of stylet IX. Gonapophyses consisting of 68-75 articles, their chaetotaxy (fig. 3H) as usual for the genus.

MATERIAL EXAMINED: Brazil: Amazônia: Tarumã Mirim, near Manaus, in tree-traps, J. Adis leg. (one male, holotype, one female,
allotype, in the Instituto Nacional de Pesquisas da Amazônia (INPA); 10 paratypes and 32 additional specimens in the Instituto Nacional de Pesquisas da Amazônia (INPA) and in The American Museum of Natural History.

**ETYMOLOGY:** This species is named for its collector.

**DISCUSSION:** In the last published key to the species of *Neomachilellus* (Wygodzinsky, 1952), *N. adisi* would key out to *N. ibiti* Wygodzinsky, *N. lenti* Wygodzinsky and *N. albuquerquei* Wygodzinsky, all described from southern Brazil. *N. adisi* differs from *ibiti* by the presence of well developed pigment on the legs; absent in *ibiti*; by the much narrower distal article of the labial palp, in both sexes, and by the hypodermal pigment arranged in a dark, narrow longitudinal band on the second article of the maxillary palp, very faint in *ibiti*. *N. adisi* can be distinguished from *N. lenti* by the relatively short apical spine of the stylets of urosternite V, the spine being as long as the stylet itself in *lenti*; by the very short setae of the under surface of the hind tibiae, much longer in *lenti*; by the absence of a field of short spiniform setae on the apical portion of the second article of the maxillary palp of the male, present in *lenti*, and by the slightly but distinctly darkened intermediate jointlets of the flagellum of the antennae, concolorous with the chains in *lenti*. Finally, *N. adisi* can be distinguished from *N. albuquerquei* by the much more extensive pigment on the maxillary palp; by the presence of pigment on the legs, almost absent in *albuquerquei*; by the very short setae on the under surface of the hind tibiae, much longer in *albuquerquei*, and by the smaller field of short semierect setae on the apex of the second article of the maxillary palp of the male.

**Neomachilellus scandens**, sp. n.  
(Figures 1B, 4, 5)

Maximum observed body length 12 mm.; maximum length of antennae 17 mm, of terminal filament 13 mm. Color of body yellowish white; hypodermal pigment on head, mouthparts, antennae and legs. Color pattern formed by scales, unknown.

Head with 1+1 pigment spots between ocelli (fig. 4F) and 1+1 spots behind ocelli.

Coxite IX with stylet. I. Apex of hind tibia. J. Apex of second article of maxillary palp. K. Apex of penis. L. Center of hind border of urosternite VIII. — Wygodzinsky del.**
Color pattern of eyes (fig. 4G) consisting of large diffuse spots (probably better defined in live specimens). Eyes (fig. 4E-G) slightly wider than long (length/width = 1/1.1; their line of contact equal to three fifths their length. Ocelli only slightly shorter than anterior border of eyes, narrowly sole-shaped (figs. 1B, 4E, F). Head capsule not sexually dimorphic.

Antennae longer than body. Scapus with pigment arranged as in figure 1B, characterized by wide subapical, darkly pigmented, transverse marking. Flagellum light brown, with intermediate jointlets concolorous (fig. 4C) with chains or slightly darker. Pigment pattern of mandibles as shown in figure 5H. Maxillary palp as shown in figures 4A, 5A, their pigment pattern characterized by hourglass-shaped, in some cases interrupted dark marking on second article (figs. 1B, 4A, 5A). Second article of palp of male with slightly sclerotized process beset with several long setae (fig. 4J); inner surface of apex of article only with scattered hairs, specialized setae absent. Remaining articles without special features, seventh as long as penultimate. Labial palpi narrowly bordered with pigment along anterior surface (figs. 4D, 5G). Terminal article of labial palp strongly widened in both sexes, almost twice as long as wide in male.

Pigmentation of legs as shown in figure 5B. C, similar in both sexes, characterized by wide extension of pigment on tibiae, especially on fore legs. Femora and tibiae without spine-like setae, although some present on tarsi. Under surface of posterior tibiae with dense, slender, medium-sized setae (fig. 4I).

Styles of ninth segment of male six seventh as long as coxite, in female two thirds as long as coxite. Distal spine of styles V...
Penis as illustrated (fig. 4K). Ovipositor attaining or slightly surpassing level of apex of terminal spine of stylets IX. Gonapophyses consisting of 55-60 articles, their chaetotaxy (fig. 5D) as usual for the genus.

MATERIAL EXAMINED: Brazil: Amazônia: Tarumã Mirim, near Manaus, in tree traps, J. Adis leg. (one male, holotype, one female, allotype, in the Instituto Nacional de Pesquisas da Amazônia (INPA) Manaus; 11 paratypes and 42 additional specimens in the Instituto Nacional de Pesquisas da Amazônia (INPA) and The American Museum of Natural History, New York).

ETHNOLOGY: From the Latin scando, climb, in allusion to the arboreal way of life of the species.

DISCUSSION: Neomachilellus scandens also keys out to *N. ibiti*, *N. lenti* and *N. albuquerquei*. *N. scandens* can be distinguished from *ibiti* by the relative length of the terminal article of the maxillary palp, equal in length to the penultimate article in *scandens* but distinctly shorter than the penultimate in *ibiti*, and by the apical spine of stylet V, about two thirds as long as the stylet proper in *scandens* and much shorter in *ibiti*. *N. scandens* differs from *N. lenti* by the absence, in the male, of a group of short spiniform setae on the apex of the second article of the maxillary palp, present in *lenti*, and by the relative size of the terminal article of the maxillary palp of both sexes, as long as the penultimate in *scandens* but much shorter than the penultimate in *lenti*. Finally, *N. scandens* is distinguished from *N. albuquerquei* by the apical spine of the stylets V, two thirds as long as the stylet proper in *scandens* but only about half as long as the stylet in *albuquerquei*. In *albuquerquei*, the terminal article of the maxillary palp is much shorter than the penultimate, but about as long as the penultimate in *scandens*. Conspicuous hypodermal pigment is present on articles I-IV of the maxillary palp in *scandens*, but only on articles I-V in *albuquerquei*.

*Neomachilellus adisi* and *N. scandens* are occasionally collected together and are clearly sympatric in the Manaus area. The two species can be distinguished as follows:

1. Eye pattern consisting of transverse stripes (fig. 2A); pigment of scapus forming large longitudinal band (fig. 1A); second article of maxillary palp of male with pigment arranged in shape of longitudinal stripe (figs. 1A, 2E); fore tibia with pigment arranged in longitudinal stripe (fig. 2G); apical spine of stylet proper (fig. 3G); terminal spine of stylet IX one fourth as long as stylet proper (fig. 2H) ........ *adisi*

— Eye pattern consisting of large diffuse spots (fig. 4G); pigment of scapus forming

large subapical annulus (fig. 1B); second article of maxillary palp of male with pigment arranged in hourglass-shaped spot (figs. 1B, 5A); fore tibia almost entirely pigmented (fig. 5C); apical spine of stylet V two thirds as long as stylet proper (fig. 5F); terminal spine of stylet IX one half as long as stylet proper (fig. 5E)...

Sumário

São descritas duas espécies novas de Microcoryphia, Neomachilellas adisi e N. Scandens que ocorrem nos igapós perto de Manaus. Foram coletadas em armadilhas colocadas nas árvores. Essas novas espécies são comparadas com outras espécies do gênero que, até este relato, era apenas conhecido do sul do Brasil.
