Summary
We propose a new discrete element method supporting general polyhedral meshes. The method can be understood as a lowest-order discontinuous Galerkin method parametrized by the continuous mechanical parameters (Young’s modulus and Poisson’s ratio). We consider quasistatic and dynamic elastoplasticity, and in the latter situation, a pseudoenergy-conserving time-integration method is employed. The computational cost of the time-stepping method is moderate since it is explicit and used with a naturally diagonal mass matrix. Numerical examples are presented to illustrate the robustness and versatility of the method for quasistatic and dynamic elastoplastic evolutions.

1 INTRODUCTION

Discrete element methods (DEM) constitute a large class of particle methods which have originally been used for crystalline materials1 and geotechnical problems2 and have found applications in granular materials, soil and rock mechanics. In their original formulation, DEM consisted in representing a domain by small spherical particles interacting by means of forces and torques. A wide range of models for the expression of these bonds has been developed depending on the material constitutive law. Computing the deformation of the domain then consists in computing the evolution of the particle system. Advantages of DEM are their ability to deal with discontinuous materials, such as fractured or porous materials, as well as the possibility to take advantage of GPU computations.3 Other, similar, particle methods have been derived in the context of smooth particles hydrodynamics methods, which require an interaction kernel.4 The main difficulty in DEM consists in deriving a correct set of forces between elements to discretize the continuous equations (in the present case, dynamic elastoplasticity). DEM originally used sphere packing to discretize the domain5 and were forced to fit parameters in order to obtain relevant values for the Young modulus E or the Poisson ratio ν.6,7 Moreover, simulating a material with a Poisson ratio ν larger than 0.3 met with difficulties.8 Note also the possibility to use DEM only in a limited zone, where crack occurs, for instance, in order to mitigate these issues. For example, a modified DEM has been coupled with a virtual element method for elasticity to discretize fracturing porous media.9

A DEM was developed in Reference 10 and was formally proved to be consistent with Cauchy elasticity. A first attractive feature of this method was that the discrete force parameters were directly derived from the Young modulus and the Poisson ratio without the need for a fitting process. Moreover, the method exhibited robustness in the incompressibility limit (ν → 0.5). Similar ideas have been used to handle brittle fracture.11 However, several limitations remain in this approach. First the evaluation of the forces between particles hinges on the use of a Voronoi mesh and does not adapt
to general (not even tetrahedral) meshes. This is due to a nearest-neighbor evaluation of the gradient on a facet of the mesh (known in the Finite Volume community as the “two-point flux problem”). Second, the expression of the forces for a Cauchy continuum cannot be readily extended to more general behavior laws. Finally, the convergence proof is mostly formal (on a Cartesian grid) and no convergence proof is given on general (Voronoi) meshes, apart from numerical evidence.

The main goal of the present contribution is to circumvent the above issues by extending the discrete element method of Reference 10 to general polyhedral meshes and elastoplastic behavior laws. The present space-discretization scheme involves a diagonal mass matrix and shares a number of properties with finite volume12,13 and lowest-order discontinuous Galerkin (dG) methods.14 Specifically we use piecewise constant gradient reconstructions in each mesh cell evaluated from local displacement reconstructions at the facets of the mesh. As a consequence, the present DEM is not a mesh-free method since it uses the mesh geometry to compute the above reconstructions. However, it can still be viewed as a particle method owing to the use of a diagonal mass matrix. In addition to the displacement unknowns, volumetric unknowns representing plastic strains are also added. We devise the scheme for both quasistatic and dynamic elastoplasticity, and in the latter situation we perform the time discretization using the explicit pseudoenergy conserving time-integration method developed in Reference 15. There are two main differences with Reference 13 regarding the discretization of the elliptic (here linear elastic) part. On the one hand13 uses only cell dofs, whereas the present DEM uses also boundary vertex dofs for the displacement. As we shall see below, the introduction of boundary vertex dofs can have a sizable impact on tempering the CFL restriction on the time step in the context of explicit time-marching methods. On the other hand the mass distribution of the present DEM is different. Our choice is motivated by the fact that, to use an explicit integration with a diagonal mass matrix, every dof needs a mass to compute its velocity, even dofs on boundary vertices. Moreover, numerical results are presented to illustrate the robustness and versatility of the proposed method in two and three space dimensions. Finally, we mention that the convergence of the scheme can be studied using the framework of gradient discretization methods (GDM).16 GDM lead to a unified and powerful framework allowing one to prove convergence and error estimates for a wide range of numerical schemes.

This article is organized as follows. Section 2 briefly recalls the equations of dynamic elastoplasticity in a Cauchy continuum. Section 3 introduces the proposed DEM and presents the space discretization of the governing equations. Some numerical tests to verify the convergence of the space discretization in a steady setting are reported. Section 4 deals with the DEM discretization for quasistatic elastoplasticity and presents test cases in two and three space dimensions. Section 5 addresses the time discretization of the dynamic elastoplasticity problem using the explicit pseudoenergy conserving time-integrator developed in Reference 15. This section also assesses the coupled DEM and time discretization on test cases in three space dimensions. Finally Section 6 draws some conclusions.

2 | GOVERNING EQUATIONS FOR DYNAMIC ELASTOPLASTICITY

We consider an elastoplastic material occupying the domain \( \Omega \subset \mathbb{R}^d \), \( d \in \{2,3\} \), in the reference configuration and evolving dynamically on the finite time interval \( (0,T), \ T > 0 \), under the action of volumetric forces and boundary conditions. The strain regime is restricted to small strains so that the linearized strain tensor is \( \varepsilon(u) := \frac{1}{2}(\nabla u + (\nabla u)^T) \), where \( u \) is the displacement field. The plastic constitutive law hinges on a von Mises criterion with nonlinear isotropic hardening. The material is supposed to be homogeneous, isotropic and rate-independent. The present formalism can be extended to the case of anisotropic, inhomogeneous, rate-dependent, anisothermal materials as well as finite strains. The stress tensor \( \sigma \in \mathbb{R}^{d\times d}_{\text{sym}} \) is such that

\[
\sigma := C : (\varepsilon(u) - \varepsilon_p),
\]

(1)

where \( C \) is the fourth-order stiffness tensor, the subscript sym stands for symmetric tensors and \( \varepsilon_p \in \mathbb{R}^{d\times d}_{\text{sym}} \) is the (trace-free) tensor of remanent plastic strain. The von Mises yield function \( \varphi \) is given by

\[
\varphi(\sigma, p) := \sqrt{\frac{3}{2} \left| \text{dev}(\sigma) \right| - (\sigma_0 + R(p))},
\]

(2)
where \( \text{dev}(\sigma) \) is the deviatoric part of \( \sigma \) and \( |\tau| = (\sum_{i=1}^{d} \tau_{ij}^2)^{\frac{1}{2}} \) for a second-order tensor \( \tau \), \( p \) is the scalar cumulated plastic deformation, \( R(p) := \frac{dp}{d\bar{p}} \) where the function \( \omega_p \) is the part of the Helmholtz free energy related to isotropic hardening, and \( \sigma_0 \) is the initial yield stress, so that the actual yield stress is \( \sigma_0 + R(p) \). Admissible states are characterized by the inequality \( \varphi(\sigma, p) \leq 0 \), the material is in the elastic domain if \( \varphi(\sigma, p) < 0 \) and in the plastic domain if \( \varphi(\sigma, p) = 0 \).

In strong form, the dynamic elastoplasticity equations consist in searching for the displacement field \( u : (0, T) \times \Omega \to \mathbb{R}^d \), the remanent plastic strain tensor \( \varepsilon_p : (0, T) \times \Omega \to \mathbb{R}^{d \times d}_{\text{sym}} \), and the scalar cumulated plastic deformation \( p : (0, T) \times \Omega \to \mathbb{R} \) such that the following equations hold in \( \Omega \) for all \( t \in (0, T) \):

\[
\begin{cases}
    \rho \ddot{u} - \text{div}(\sigma) = f, \\
    \lambda \geq 0, \quad \varphi(\sigma, p) \leq 0, \quad \lambda \varphi(\sigma, p) = 0, \\
    \dot{p} = \lambda, \quad \dot{\varepsilon}_p = \lambda \frac{\partial \varphi}{\partial \sigma}(\sigma),
\end{cases}
\]

where \( \rho > 0 \) is the density of the material, dots indicate time derivatives, \( f \) is the imposed volumetric force, and \( \lambda \) is the Lagrange multiplier associated with the constraint \( \varphi(\sigma, p) \leq 0 \). Note that owing to (2), we have \( \dot{\varepsilon}_p = \lambda \sqrt{\frac{2}{2 \pi}} |\text{dev}(\sigma)| \), so that 

\( \dot{p} = \lambda = \sqrt{\frac{2}{2 \pi}} |\text{dev}(\sigma)| \).

Let \( \partial \Omega = \partial \Omega_N \cup \partial \Omega_D \) be a partition of the boundary of \( \Omega \). By convention \( \partial \Omega_D \) is a closed set and \( \partial \Omega_N \) is a relatively open set in \( \partial \Omega \). The boundary \( \partial \Omega_D \) has an imposed displacement \( u_D \), whereas a normal stress \( g \) is imposed on \( \partial \Omega_N \), that is, we enforce

\[
u = u_D \text{ on } (0, T) \times \partial \Omega_D, \quad \sigma \cdot n = g_N \text{ on } (0, T) \times \partial \Omega_N.
\]

We also set

\[
V_D := \{ v \in H^1(\Omega; \mathbb{R}^d) \mid v_{|\partial \Omega_D} = u_D \}, \quad V_0 := \{ v \in H^1(\Omega; \mathbb{R}^d) \mid v_{|\partial \Omega_N} = 0 \}.
\]

(Note that the space \( V_D \) is actually time-dependent if the Dirichlet data is time-dependent.) We also set

\[
Q := L^2(\Omega; \mathbb{R}^{d \times d}_{\text{sym}}), \quad Q_0 := \{ \eta_p \in Q \mid \text{tr}(\eta_p) = 0 \}.
\]

where \( P := L^2(\Omega) \). Here, for any vector space \( S \), \( L^2(\Omega; S) \) is the Hilbert space composed of \( S \)-valued square-integrable functions in \( \Omega \), and \( H^1(\Omega; S) \) is the subspace of \( L^2(\Omega; S) \) composed of those functions whose weak gradient is also square-integrable. All of the above functional spaces are equipped with their natural inner product. Then the weak solution is searched as a triple \((u, \varepsilon_p, p) : (0, T) \to V_D \times Q_0 \times P\). To alleviate the mathematical formalism, we do not specify here the regularity in time (see References 17 and 18). We introduce the mass bilinear form such that

\[
m(a, \tilde{v}) := \langle \rho a, \tilde{v} \rangle_{V'_0, V_0}, \quad \forall (a, \tilde{v}) \in V'_0 \times V_0,
\]

where \( V'_0 \) denotes the dual space of \( V_0 \) and \( \langle \cdot, \cdot \rangle_{V'_0, V_0} \) the duality pairing, and the stiffness bilinear form parameterized by a member \( \eta_p \in Q_0 \) such that

\[
a(\eta_p; v, \tilde{v}) := \int_{\Omega} \left( C : (\varepsilon(v) - \eta_p) \right) : \varepsilon(\tilde{v}), \quad \forall (v, \tilde{v}) \in V_D \times V_0,
\]

The governing equations (3) are rewritten as follows: Find \((u, \varepsilon_p, p) : (0, T) \to V_D \times Q_0 \times P\) such that, for all \( t \in (0, T) \),

\[
\begin{cases}
    m(\ddot{u}(t); \tilde{v}) + a(\varepsilon_p(t); u(t), \tilde{v}) = l(t; \tilde{v}), \quad \forall \tilde{v} \in V_0, \\
    \lambda \geq 0, \quad \varphi(\sigma, p) \leq 0, \quad \lambda \varphi(\sigma, p) = 0, \quad \text{in } \Omega, \\
    \dot{p} = \lambda, \quad \dot{\varepsilon}_p = \lambda \frac{\partial \varphi}{\partial \sigma}(\sigma), \quad \text{in } \Omega,
\end{cases}
\]
where the time-dependency is left implicit in the second and third equations, and with the linear form \( l(t; \cdot) \) acting on \( V_0 \) as follows:

\[
l(t; \tilde{v}) := \int_{\Omega} f_0(t) \cdot \tilde{v} + \int_{\partial \Omega} g_N(t) \cdot \tilde{v}.
\]  

(10)

Note that the Dirichlet condition is enforced strongly, whereas the Neumann condition is enforced weakly. Define the elastic energy \( E_{\text{elas}}(t) := \frac{1}{2} \int_{\Omega} \sigma(t) : C^{-1} : \sigma(t) \) with \( \sigma(t) := \nabla (u(t) - \varepsilon_p(t)) \), the kinetic energy \( E_{\text{kin}}(t) := \frac{1}{2} m (\dot{u}(t), \dot{u}(t)) \), the plastic dissipation \( E_{\text{plas}}(t) := \int_{\Omega} \sigma_0 p(t) + \omega p(p(t)) \), and the work of external loads \( E_{\text{ext}}(t) := \int_0^t l(s; \dot{u}(s)) ds \). Then assuming for simplicity a homogeneous Dirichlet condition, and recalling the assumption \( p(0) = 0 \), we have the following energy equation:

\[
E_{\text{elas}}(t) + E_{\text{kin}}(t) + E_{\text{plas}}(t) = E_{\text{ext}}(t) + E_{\text{elas}}(0) + E_{\text{kin}}(0),
\]  

(11)

showing that the total energy at time \( t \) is balanced with the work of external loads up to time \( t \) (notice that \( E_{\text{plas}}(0) = 0 \) in our setting).

### 3 | SPACE SEMIDISCRETIZATION

In this section, we present the DEM space semidiscretization of the weak formulation (9), and we present a few verification test cases for static linear elasticity.

#### 3.1 | Degrees of freedom

The domain \( \Omega \) is discretized with a mesh \( T_h \) of size \( h \) made of polyhedra with planar facets in three space dimensions or polygons with straight edges in two space dimensions. We assume that \( \Omega \) is itself a polyhedron or a polygon so that the mesh covers \( \Omega \) exactly, and we also assume that the mesh is compatible with the partition of the boundary \( \partial \Omega \) into the Dirichlet and Neumann parts.

Let \( C \) denote the set of mesh cells and \( Z^d \) the set of mesh vertices sitting on the boundary of \( \Omega \). Vector-valued volumetric degrees of freedom (dofs) for a generic displacement field \( v_c := (v_c)_{c \in C} \in \mathbb{R}^{d(b)} \) are placed at the barycenter of every mesh cell \( c \in C \), where \#(S) denotes the cardinality of any set \( S \). Additional vector-valued boundary degrees of freedom \( v_{z^a} := (v_{z^a})_{z^a \in Z^a} \in \mathbb{R}^{d(b)} \) for the displacement are added at every boundary vertex \( z \in Z^a \). The reason why we introduce boundary vertex dofs is motivated in Section 3.3. These dofs are also used to enforce the Dirichlet condition on \( \partial \Omega_D \). We use the compact notation \( v_h := (v_c, v_{z^a}) \) for the collection of all the cell dofs and all the boundary vertex dofs. Figure 1 illustrates the position of the displacement dofs. In addition a (trace-free) symmetric tensor-valued dof representing the internal plasticity variable \( \eta_{p,c} \in \mathbb{R}^{d(b)} \) is attached to every mesh cell \( c \in C \), as well as a scalar dof \( p_c \) representing the cumulated plastic deformation. We write \( \eta_{p,c} := (\eta_{p,c})_{c \in C} \in Q_h := (\mathbb{R}^{d(b)})^{#(C)} \) and \( p_c := (p_c)_{c \in C} \in P_h := \mathbb{R}^{#(C)} \).
Let \( F \) denote the set of mesh facets. We partition this set as \( F = F^i \cup F^b \), where \( F^i \) is the collection of the internal facets shared by two mesh cells and \( F^b \) is the collection of the boundary facets sitting on the boundary \( \partial \Omega \) (such facets belong to the boundary of only one mesh cell). Using the cell and boundary-vertex dofs introduced above, we reconstruct a collection of displacements \( v_F := (v_F)_{F \in F} \in \mathbb{R}^{d(F)} \) on the mesh facets. The facet reconstruction operator is denoted \( R \) and we write

\[
v_F := R(v_h).
\]

The precise definition of the facet reconstruction operator is given in Section 3.3. Using the reconstructed facet displacements and a discrete Stokes formula, it is possible to devise a discrete \( \mathbb{R}^{d \times d} \)-valued piecewise-constant gradient field for the displacement that we write \( G_c(v_F) := (G_c(v_F))_{c \in C} \in \mathbb{R}^{d \times d(C)} \). Specifically we set in every mesh cell \( c \in C \),

\[
G_c(v_F) := \sum_{F \in \partial c} \frac{|F|}{|c|} v_F \otimes n_{F,c}, \quad \forall v_F \in \mathbb{R}^{d(F)},
\]

where the summation is over the facets \( F \) of \( c \) and \( n_{F,c} \) is the outward normal to \( c \) on \( F \). Note that for all \( v_h \in V_h \), we have

\[
G_c(R(v_h)) = \sum_{F \in \partial c} \frac{|F|}{|c|} (R(v_h)_F - v_c) \otimes n_{F,c}.
\]

since \( \sum_{F \in \partial c} |F| n_{F,c} = 0 \). We define a constant linearized strain tensor in every mesh cell \( c \in C \) such that

\[
\epsilon_c(v_F) := \frac{1}{2} (G_c(v_F) + G_c(v_F)^T) \in \mathbb{R}^{d \times d}.
\]

Finally, we define two additional reconstructions. The first is a cellwise nonconforming \( P^1 \) reconstruction \( \mathfrak{R} \) defined for all \( c \in C \) by

\[
\mathfrak{R}(v_h)_c(x) := v_c + G_c(R(v_h)) \cdot (x - x_c),
\]

where \( x \in c \) and \( x_c \) is the barycenter of the cell \( c \). The second is a \( P^1 \) reconstruction on boundary facets, written \( \mathfrak{R}^d(v_{z^c}) \), and computed using the vertex dofs of the boundary facets. In case of simplicial facets, it reduces to classical \( P^1 \) Lagrange interpolation. For nonsimplicial facets, generalized barycentric coordinates need to be used, see Reference 19, for instance.

### 3.2 | Discrete problem

Let us set \( V_h := \mathbb{R}^{d(C)} \times \mathbb{R}^{d(z^c)} \) and (recall that \( \partial \Omega_D \) is a closed set)

\[
\begin{align*}
V_{hD} & := \{ v_h \in V_h \mid v_c = u_D(z) \ \forall z \in Z^d \cap \partial \Omega_D \}, \\
V_{ho} & := \{ v_h \in V_h \mid v_c = 0 \ \forall z \in Z^d \cap \partial \Omega_D \}, \\
W_{hD} & := \{ v_h \in V_h \mid v_c = u_D(z) \ \forall z \in Z^d \cap \partial \Omega_D \}.
\end{align*}
\]

(Note that the spaces \( V_{hD} \) and \( W_{hD} \) are actually time-dependent if the Dirichlet data is time-dependent.) The discrete stiffness bilinear form is parameterized by a member \( \eta_{p,c} \in Q_h \) and is such that, for all \( (v_h, \tilde{v}_h) \in V_{hD} \times V_{ho} \) (compare with (8)),

\[
a_h(\eta_{p,c}; v_h, \tilde{v}_h) := \sum_{c \in C} |c| \left( C : (\epsilon_c(R(v_h)) - \eta_{p,c}) \right) : \epsilon_c(R(\tilde{v}_h)) + s_h(v_h, \tilde{v}_h).
\]

Here \( s_h \) is a weakly consistent stabilization bilinear form intended to render \( a_h \) coercive and which is defined on \( V_h \times V_h \) as follows:
\[
s_h(v_h, \tilde{v}_h) = \sum_{F \in \mathcal{F}} \frac{\eta}{h_F} [F][[\mathcal{R}(v_h)]_F \cdot [\mathcal{R}(\tilde{v}_h)]_F
\]

where \( h_F \) is the diameter of the facet \( F \in \mathcal{F} \). For an interior facet \( F \in \mathcal{F}^i \), writing \( c_- \) and \( c_+ \) the two mesh cells sharing \( F \), that is, \( F = \partial c_- \cap \partial c_+ \), and orienting \( F \) by the unit normal vector \( n_F \) pointing from \( c_- \) to \( c_+ \), one has

\[
[\mathcal{R}(v_h)]_F := \mathcal{R}(v_h)_{c_+}(x_F) - \mathcal{R}(v_h)_{c_-}(x_F).
\]

The sign of the jump is irrelevant in what follows. The role of the summation over the interior facets in (19) is to penalize the jumps of the cell reconstruction \( \mathcal{R} \) across the interior facets. For a boundary facet \( F \in \mathcal{F}^b \), we denote \( c_- \) the unique mesh cell containing \( F \), we orient \( F \) by the unit normal vector \( n_F := n_{c_-} \) which points outward \( \Omega \), and we define

\[
[\mathcal{R}(v_h)]_F := \mathcal{R}^d(v_Z^e)_F(x_F) - \mathcal{R}(v_h)_{c_-}(x_F).
\]

The role of the summation over the boundary facets in (19) is to penalize the jumps between the cell reconstruction \( \mathcal{R} \) and the boundary facet reconstruction \( \mathcal{R}^d \). The parameter \( \eta > 0 \) in (19) is user-defined with the only requirement that \( \eta > 0 \). The bilinear form \( s_h \) is classical in the context of discontinuous Galerkin methods (see References 20,21, for instance, see also Reference 14 for cell-centred Galerkin methods). In practice, the penalty parameter \( \eta \) scales as \( \eta = \beta \mu \) where \( \mu \) is the second Lamé coefficient of the material and \( \beta \) is a dimensionless factor that remains user-dependent. Notice that this choice is robust with respect to \( \nu \to 0.5 \). We present a numerical test in Section 3.5.1 illustrating the moderate impact of \( \beta \) on the numerical computations.

We can next define a discrete mass bilinear form \( m_h \) similar to (7) and a discrete load linear form \( l_h^e(t) \) similar to (10); details are given below. Then the space semidiscrete version of the evolution problem (9) amounts to seeking \((u_h, \epsilon_p,c,p_c) : (0,T) \to V_{hd} \times Q_h \times P_h \) such that, for all \( t \in (0,T) \),

\[
\begin{aligned}
& m_h(\dot{u}_h(t), \ddot{v}_h) + a_h(\epsilon_{p,c}(t); u_h(t), \ddot{v}_h) = l_h(t, \ddot{v}_h), \quad \forall \ddot{v}_h \in V_{h0}, \\
& \lambda_c \geq 0, \quad \phi(\Sigma_c(\dot{u}_h), p_c) \leq 0, \quad \lambda_c \phi(\Sigma_c(\dot{u}_h), p_c) = 0, \quad \forall c \in C, \\
& \dot{p}_c = \lambda_c, \quad \dot{\epsilon}_{p,c} = \lambda_c \frac{\partial \phi}{\partial \sigma}(\Sigma_c(\dot{u}_h)), \quad \forall c \in C,
\end{aligned}
\]

where the time-dependency is left implicit in the second and third equations and where we introduced in every mesh cell \( c \in C \) the local stress tensor

\[
\Sigma_c(\dot{u}_h) := \mathbb{C} : (\dot{\epsilon}_c(\mathcal{R}(u_h)) - \epsilon_{p,c}) \in \mathbb{R}^{d \times d}_{sym}.
\]

Note that the plasticity relations in (22) are enforced cellwise, that is, a mesh cell \( c \in C \) is either in the elastic state or in the plastic state depending on the value of \( \phi(\Sigma_c(\dot{u}_h), p_c) \). This is due to the fact that stresses are cell-wise constant and thus the second relation of (22) can only be enforced cell-wise.

The definition of the discrete mass bilinear form \( m_h(\cdot, \cdot) \) and \( l_h^e(t; \cdot) \) can be written as follows for all \((v_h, \ddot{v}_h) \in V_h \times V_h \) (compare with (7) and (10)):

\[
\begin{aligned}
& m_h(v_h, \ddot{v}_h) := \sum_{v \in \mathcal{V}} m_z v \cdot \ddot{v}_z + \sum_{c \in C} m_c v_c \cdot \ddot{v}_c, \\
& l_h(t, \ddot{v}_h) := \sum_{c \in C} f_c(t) \cdot \ddot{v}_c + \sum_{F \in \mathcal{F}^b \cap \Omega_h} g_F(t) \cdot \mathcal{R}(\ddot{v}_h)_F,
\end{aligned}
\]

with \( m_z := \int_{\omega_z} \rho \), \( m_c := \int_{\omega_z} \rho \), \( f_c(t) := \int f(t) \) and \( g_F(t) := \int g_N(t) \).
3.3 | Reconstruction operator on facets

The reconstruction operator $\mathcal{R}$ is constructed in the same way as in the finite volume methods studied in Reference 13, Sec. 2.2 and in the cell-centered Galerkin methods from Reference 14. For a given facet $F \in \mathcal{F}$, we select neighboring boundary vertices collected in a subset denoted $\mathcal{Z}_F^\partial$ and neighboring cells collected in a subset denoted $\mathcal{C}_F$, as well as coefficients $(\alpha_z^F)_{z \in \mathcal{Z}_F^\partial}$ and $(\alpha_c^F)_{c \in \mathcal{C}_F}$, and we set

$$
\mathcal{R}(v_h)_F := \sum_{z \in \mathcal{Z}_F^\partial} \alpha_z^F v_z + \sum_{c \in \mathcal{C}_F} \alpha_c^F v_c, \quad \forall v_h \in V_h. \quad (26)
$$

The neighboring dofs should stay $O(h)$ close to the facet $F$. An algorithm is detailed thereafter to explain the selection of the neighboring dofs in $\mathcal{Z}_F^\partial$ and $\mathcal{C}_F$. The coefficients $\alpha_z^F$ and $\alpha_c^F$ are chosen as the barycentric coordinates of the facet barycenter $x_F$ in terms of the location of the boundary vertices in $\mathcal{Z}_F^\partial$ and the barycenter $\mathcal{S}$s of the cells in $\mathcal{C}_F$. For any interior facet $F \in \mathcal{F}^i$, the set $\mathcal{Z}_F^\partial \cup \mathcal{C}_F$ is constructed so as to contain exactly $(d+1)$ points forming the vertices of a nondegenerate simplex. Thus, the barycentric coefficients $\alpha_z^F$ and $\alpha_c^F$ are computed by solving the linear system:

$$
\begin{cases}
\sum_{z \in \mathcal{Z}_F^\partial} \alpha_z^F + \sum_{c \in \mathcal{C}_F} \alpha_c^F = 1, \quad \forall F \in \mathcal{F}, \\
\sum_{z \in \mathcal{Z}_F^\partial} \alpha_z^F z + \sum_{c \in \mathcal{C}_F} \alpha_c^F x_c = x_F, \quad \forall F \in \mathcal{F},
\end{cases} \quad (27)
$$

where the vertex and its position are written $z$ and $x_c$ is the position of the barycenter of the cell $c$.

The main rationale for choosing the neighboring dofs is to ensure as much as possible that all the coefficients $\alpha_z^F$ or $\alpha_c^F$ lie in the interval $(0,1)$, so that the definition of $\mathcal{R}(v_h)_F$ in (26) is based on an interpolation formula (rather than an extrapolation formula if some coefficients lie outside the interval $(0,1)$.) For most internal facets $F \in \mathcal{F}^i$, far from the boundary $\partial \Omega$, it is possible to choose an interpolation-based reconstruction operator using only cell dofs, that is, we usually have $\mathcal{Z}_F^\partial := \emptyset$. Figure 3 presents an example for an interior facet $F$ using three neighboring cell dofs located at the cell barycenters $x^i$, $x^j$, and $x^k$. Close to the boundary $\partial \Omega$, the use of boundary vertex dofs helps to prevent extrapolation. In all the cases we considered, interpolation was always possible using the algorithm described below.

On the boundary facets, the reconstruction operator only uses interpolation from the boundary vertices of the facet, that is, we always set $\mathcal{C}_F := \emptyset$ for all $F \in \mathcal{F}^b$. In three space dimensions, the facet can be polygonal and the barycentric coordinates are generalized barycentric coordinates. This is achieved using$^{19}$ and the package 2D Triangulation of the geometric library CGAL. In the case of simplicial facets (triangles in three space dimensions and segments in two space dimensions), we recover the classical barycentric interpolation as described above.
The advantage of using interpolation rather than extrapolation is relevant in the context of explicit time-marching schemes where the time step is restricted by a CFL condition depending on the largest eigenvalue $\lambda_{\text{max}}$ of the stiffness matrix associated with the discrete bilinear form $a_h(\cdot;\cdot)$ (see, eg, (48)). It turns out that using extrapolation can have an adverse effect on the maximal eigenvalue of the stiffness matrix, thereby placing a severe restriction on the time step, and this restriction is significantly alleviated if enough neighboring dofs are used in (26) to ensure that interpolation is being used. We refer the reader to Table 1 below for an illustration.

Let us now briefly outline the algorithm used for selecting the reconstruction dofs associated with a given mesh inner set for the set of particles. Note that if $\mathbf{x}_F$ lies in the convex hull of the set $(\mathbf{x}_i)_{1 \leq i \leq I}$, we use the ConvexHull structure of the scipy.spatial module of Python.

1. Compute a list of points $(\mathbf{x}_i)_{1 \leq i \leq I}$ ordered by increasing distance to $\mathbf{x}_F$; each point can be either the barycenter of a mesh cell or a boundary vertex. To this purpose, we use the KDTTree structure of the scipy.spatial module of Python.

2. Check if $\mathbf{x}_F$ lies in the convex hull of the set $(\mathbf{x}_i)_{1 \leq i \leq I}$. To this purpose we use the ConvexHull structure of scipy.spatial. If that is not true, then extrapolation must be used. Otherwise find a subset of $(\mathbf{x}_i)_{1 \leq i \leq I}$ containing $(d + 1)$ points and use the barycentric coordinates of the resulting simplex to evaluate the interpolation coefficients to be used in (26).

Note that $I$ must be large enough to enable the recovery of at least one simplex per inner facet that is not too flat, independently of the use of extrapolation or interpolation. In our computations, we generally took $I = 10$ if $d = 2$ and $I = 25$ if $d = 3$.

To illustrate the performance of the above algorithm in alleviating time step restrictions based on a CFL condition, we report in Table 1 the largest eigenvalue $\lambda_{\text{max}}$ of the stiffness matrix and the percentage of the mesh facets where extrapolation has to be used as a function of the integer parameter $I$ from the above algorithm. The results are obtained on the two three-dimensional (3D) meshes (called “coarse” and “fine”) considered in Section 5.3.1 together with the DEM discretization for the dynamic elastoplastic evolution of a beam undergoing flexion. Note that the minimal value is $I = 7$ for the coarse mesh and $I = 9$ for the fine mesh.

### Table 1

| mesh | $I = 7$ | $I = 9$ | $I = 12$ | $I = 15$ | $I = 18$ |
|------|---------|---------|---------|---------|---------|
| coarse | $4 \cdot 10^9$ | $6 \cdot 10^9$ | $4 \cdot 10^9$ | $7 \cdot 10^9$ | $2 \cdot 10^9$ | $0\%$ | $2 \cdot 10^9$ | $0\%$ |
| fine | $- \cdot -$ | $7 \cdot 10^9$ | $1.6\%$ | $3 \cdot 10^9$ | $1 \cdot 10^9$ | $0.1\%$ | $1 \cdot 10^9$ | $0.1\%$ |

Abbreviation: DEM, discrete element methods.

### 3.4 Interpretation as a DEM

In this section, we rewrite the first equation in (22) as a particle method by introducing the dofs of the discrete displacement $u_h(t) \in V_{\text{bd}}$ attached to the mesh cells and to the boundary vertices lying on the Neumann boundary, which we write $U_{\text{DEM}} := (u_h(t))_{t \in T}$ with $P := \mathbb{C} \cup \mathbb{Z}^d_C$ and $\mathbb{Z}^d_C := \{ z \in \mathbb{Z}^d ; z \in \partial \Omega_N \}$. Here $P$ can be viewed as the indexing set for the set of particles. Note that $U_{\text{DEM}}$ is a collection of dof values forming a column vector, whereas $u_h$ is a piecewise-constant function. Recall the definition of the discrete mass bilinear form, we set $m_p := \int_{\partial \Omega} \rho$ if $p = c \in C$ and $m_p := \int_{\partial \Omega} \rho$ if $p = z \in \mathbb{Z}^d_N$. Concerning the external loads, we set $F_{\text{DEM}}(t) := (F_p(t))_{p \in P}$ with $F_p(t) := f_p(t)$ if $p = z$, where $F_z \subset F^b$ is the collection of the boundary faces to which $z$ belongs and the coefficients $a^k_p$ are those used in (26) for the facet reconstruction. Since the Neumann boundary $\partial \Omega_N$ is relatively open in $\partial \Omega$, all the facets in $F_z$ belong to $\partial \Omega_N$ if $z \in \mathbb{Z}^d_C$.

Recall that $\epsilon_{p,c} : (0, T) \rightarrow \mathbb{Q}$ is the discrete tensor of remanent plastic strain. Let us use the shorthand notation $\Sigma_c(t) := \Sigma_c(u_h(t))$ as defined in (23), as well as $\Sigma_c(t) := (\Sigma_c(t))_{c \in C}$. For a piecewise-constant function defined on the mesh cells, say $\mathbf{w}_c = (\mathbf{w}_c)_{c \in C}$, we define the mean-value $\{ \mathbf{w}_c \}_F := \frac{1}{2}(\mathbf{w}_c + \mathbf{w}_c)$ for all $F = \partial c_- \cap \partial c_+ \in F^i$. Recall that the
interior facet $F$ is oriented by the unit normal vector $n_F$ pointing from $c_-$ to $c_+$ and that the jump across $F \in F^i$ is defined such that $[w_c]_F := w_c - w_{c_+}$. Recall also that for a boundary facet $F \in F^b$, $c_-$ denotes the mesh cell to which $F$ belongs and that $n_F$ is the unit normal vector to $F$ pointing outward $\Omega$. Then a direct calculation shows that for all $\bar{v}_h \in V_h$,

$$-a_h(\varepsilon_p, c(t); u_h(t), \bar{v}_h) = \sum_{F \in F^i} |F| (\{\Sigma_c(t)\}_F \cdot n_F) \cdot [\bar{v}_c]_F + \sum_{F \in F^b} |F| (\Sigma_c(t) \cdot n_F) \cdot (\bar{v}_c - \mathcal{R}(\bar{v}_h)_F) - \sum_{F \in F^b} \eta \frac{\mathcal{R}(\mathcal{R}(u_h(t)))_F}{|F|} \cdot [\mathcal{R}(\bar{v}_h)]_F. \quad (28)$$

To simplify some expressions, we are going to neglect the second term on the above right-hand side since this term is of higher order (it is essentially the product of two jumps). Recall that, by definition, the reconstruction operator $\mathcal{R}$ on a boundary facet $F \in F^b$ makes use only of the vertex dofs of that facet. Then, letting $(\bar{V}_p)_{p \in P}$ be the collection of the dofs of the discrete test function $\bar{v}_h$, we infer that

$$-a_h(\varepsilon_p, c(t); u_h(t), \bar{v}_h) \approx \sum_{p \in P} \Phi^{ep}_p(t) \cdot \bar{V}_p + \Phi^{pen}_p(t) \cdot \bar{V}_p, \quad (29)$$

where $\Phi^{ep}_p(t)$ is the elastoplastic force acting on the particle $p \in P$ and $\Phi^{pen}_p(t)$ is the force induced by the penalty and acting on the same particle. For all $c \in C$, we have $\Phi^{ep}_c(t) := \sum_{F \in F^i \cup F^b} \Phi^{ep}_{c,F}(t)$ with $F^i_c := \{ F \in F^i \mid F \subset \partial c \}$, $F^N_c := \{ F \in F^b \mid F \subset \partial c \cap \partial \Omega_N \}$, and

$$\Phi^{ep}_{c,F}(t) := \begin{cases} \iota_c F |F| (\{\Sigma_c(t)\}_F \cdot n_F) & \text{if } F \in F^i_c, \\ |F| (\Sigma_c(t) \cdot n_F) & \text{if } F \in F^N_c. \end{cases} \quad (30)$$

with $\iota_{c,F} := n_c \cdot n_F$, and for all $z \in Z^3_N$, we have

$$\Phi^{ep}_z(t) := -\sum_{F \in F^i_c} a^p z \Phi^{ep}_{c,F}(t), \quad (31)$$

with $\Phi^{ep}_{c,F}$ defined in (30) (recall that $c_-$ denotes the unique mesh cell containing the boundary facet $F \in F^b$). Note that the principle of action and reaction is encoded in the fact that $\iota_{c,F} + \iota_{c_+ F} = 0$ for all $F = \partial c_- \cap \partial c_+ \in F^i$.

**Remark 1** (Physical forces). The quantities of (30) are remarkable in the sense that they correspond to the physical force that one expects between two particles: the average of the stress in each particle multiplied by the surface shared by the two particles and contracted with the normal of the corresponding facet. Notice that this force only depends on the macroscopic material parameters and does not depend on any added microscopic parameter.

The penalty force is composed of two terms, that is, for all $p \in P$, $\Phi^{pen}_p(t) := \Phi^{pen,1}_p(t) + \Phi^{pen,2}_p(t)$. We define the first term for every cell $c \in C$ and every facet $F \in F$ such that $F \subset \partial c$ as

$$\Phi^{pen,1}_c(t) := -\iota_{c,F} \frac{\eta}{|F|} |F| (\mathcal{R}(u_h(t)))_F, \quad (32)$$

and we define it for every Neumann boundary vertex $z \in Z^3_N$, as

$$\Phi^{pen,1}_z(t) := -\sum_{F \in F^i_c} a^p z \Phi^{pen,1}_{c,F}(t). \quad (33)$$

The second term is more intricate since it is a byproduct of the extended stencil of the method. The set of facets using the dof of the particle $p \in P$ (whether cell or boundary vertex) is defined as $\mathcal{F}_p$. This means that if $F \in \mathcal{F}_p$, then
one has either $p \in C_F$ or $p \in Z^p_F$. Let us recall that for a facet $F \in \mathcal{F}$, the cell dofs used for the reconstruction $R(u_h(t))_F$ are collected in $C_F$ and the boundary vertex dofs in $Z^p_F$. Then the second penalty term writes for all $p \in \mathcal{P}$ and all $F \in \mathcal{F}_p$ as

$$\Phi^{\text{pen.2}}_{p,F}(t) := - \sum_{c,F \supset c_F \subset \partial c} \frac{\eta}{h_F} |F'| \left[ |\mathcal{R}(u_h(t))|_F - [F] \right] n_{F,c} \cdot \left( x_F - x_c \right) a_p^c,$$

where $a_p^c$ is the barycentric coordinate associated with the particle $p \in \mathcal{P}$ in the reconstruction over the facet $F$. As a consequence, the total second penalty term writes for all $p \in \mathcal{P}$ as

$$\Phi^{\text{pen.2}}_{p}(t) := \sum_{F \in \mathcal{F}_p} \Phi^{\text{pen.2}}_{p,F}(t).$$

Finally, putting everything together, we infer that the the first equation in (22) becomes

$$m_p \ddot{u}_p(t) \simeq \Phi^{\text{pen}}_{p}(t) + \Phi^{\text{pen.2}}_{p}(t) + F_p(t), \quad \forall p \in \mathcal{P}. \quad (36)$$

**Remark 2** (Matrix formulation). Let us briefly describe the matrix formulation of the space semidiscrete problem (22) in the case of elastodynamics, that is, without plasticity. For simplicity we focus on the pure Neumann problem. A matrix $\mathbf{R} \in \mathbb{R}^{d(h(F) \times d(h(P))}$ corresponding to the reconstruction operator $R$ is first constructed. Its entries are the barycentric coefficients of the dofs used for the reconstruction on the face associated with the given line of $\mathbf{R}$. The lines of $\mathbf{R}$ associated with boundary facets have, by construction, nonzero entries only for boundary vertex dofs. The linearized strain matrix $\mathbf{E} \in \mathbb{R}^{d(h(C)) \times d(h(P))}$ is composed of the tensorial coefficients $\frac{1}{2} \frac{|F|}{|c|} (\otimes n_F + n_F \otimes \mathbf{0})$ on the lines associated with the mesh cell $c \in \mathcal{C}$ and the columns associated with the facets $F \subset \partial c$. The linear elasticity matrix $\mathbf{C} \in \mathbb{R}^{d(h(C)) \times d(h(C))}$ can be written as the block-diagonal matrix where each block corresponds to the double contraction with the fourth-order elastic tensor $\mathcal{C}$ and multiplication by $|c|$. The jump matrix $\mathbf{J} \in \mathbb{R}^{d(h(F)) \times d(h(P))}$ discretizes the jumps $[\mathcal{R}(u_h)]_F$ on a facet $F$. Its assembly is not detailed for simplicity. However, it is assembled using the connectivity matrix of adjacent cells, the gradient matrix (similar to $\mathbf{E}$ but nonsymmetrized and composed of the tensorial coefficients $\frac{1}{2} \frac{|F|}{|c|} \otimes n_F$) and $\mathbf{R}$. Denoting $\mathbf{D} \in \mathbb{R}^{d(h(F)) \times d(h(P))}$ the diagonal matrix with entry $\frac{1}{2} |F|$ for the facet $F$, the stabilization matrix $\mathbf{S}$ corresponding to the bilinear form $s_h$ can be written $\mathbf{S} := J^T \mathbf{D} \mathbf{J} \in \mathbb{R}^{d(h(P)) \times d(h(P))}$. Finally, denoting $\mathbf{K} := \mathbf{R}^T \mathbf{E}^T \mathbf{C} \mathbf{E} \mathbf{R} + \mathbf{S} \in \mathbb{R}^{d(h(P)) \times d(h(P))}$ the stiffness matrix, the space semidiscrete system (22) in the case of elastodynamics reduces to $\mathbf{M} \ddot{\mathbf{u}}_{\text{DEM}}(t) + \mathbf{K} \mathbf{u}_{\text{DEM}}(t) = F_{\text{DEM}}(t)$.

### 3.5 Convergence tests for linear elasticity

The goal of this section is to briefly verify the correct implementation of the method in the case of static linear elasticity by comparing the numerical predictions using DEM with some analytical solutions and reporting the orders of convergence on sequences of uniformly refined meshes. The model problem thus consists of finding $u \in V_D$ such that

$$\int_\Omega \varepsilon(\nabla u) : \mathcal{C} : \varepsilon(\nabla \bar{u}) = \int_\Omega f \cdot \bar{u}, \quad \forall \bar{u} \in V_0. \quad (37)$$

The $L^2$-error is computed as $\|u - \mathcal{R}(u_h)\|_{L^2(\Omega)}$. The energy error is based on the reconstructed linearized strain of the discrete solution in each mesh cell and is computed as $\|u - u_h\|_{\epsilon_h} := \frac{1}{2} a_h(0; u - u_h, u - u_h)$ where $a_h$ is defined in (18). Note that this last term also contains the energy associated with the penalty bilinear form $s_h$. The convergence rates are approximated as

$$\text{order} = d \log \left( \frac{e_1}{e_2} \right) \left( \log \left( \frac{n_2}{n_1} \right) \right)^{-1}, \quad (38)$$

where $e_1, e_2$ denote the errors on the computations with mesh sizes $h_1, h_2$ and the number of dofs $n_1, n_2$. 
3.5.1 | Choice of penalty factor

In this section, we simulate the torsion of a cylinder with various values of $\eta = \beta \mu$ obtained by varying $\beta$. The geometry is the one described in Section 4.3.2. We compare the results to first-order penalized Crouzeix-Raviart finite elements (FE). A mesh of size $h = 29\text{mm}$ is chosen for both computations. The DEM computation contains 6332 vectorial displacement dofs and the Crouzeix-Raviart 11 760. The geometry and boundary conditions are similar to Figure 7. The material is supposed to be isotropic elastic with $E = 70 \cdot 10^3 \text{Pa}$ and $\nu = 0.3$. The imposed torsion angle is $\alpha = 2.1 \cdot 10^{-2}\text{rad}$. As the solution of this torsion test consists in pure shear stress, we compare in Figure 4 tr($\sigma$) and the Von Mises stress for DEM with $\beta = 1$, $\beta = 0.1$, and $\beta = 0.01$, and the reference penalized Crouzeix-Raviart computation with $\beta = 1$. We expect the Von Mises stress to be constant on the lateral side of the cylinder and the trace of the stress tensor to be zero.

We observe that the influence of the parameter $\beta$ is rather light. Indeed, the trace of the trace tensor remains of order $10^3$ and the Von Mises stress varies between similar values. We observe that the results with the penalized Crouzeix-Raviart method vary slightly less. We believe that this is due to the higher number of dofs in this computation. As a consequence, so as to have a penalty term of the same order as the elastic term, we choose $\beta = 1$ in our subsequent computations (unless explicitly mentioned).

3.5.2 | Manufactured solution

Let us consider an isotropic two-dimensional (2D) elasticity test case in the domain $(-\frac{1}{2}, \frac{1}{2}) \times m^2$ with the Young modulus $E = 70 \cdot 10^3 \text{Pa}$ and the Poisson ratio $\nu = 0.3$. The reference solution is $u(x, y) = \frac{a}{2}(x^2 + y^2)(e_x + e_y)$ with $a = 0.8m^{-1}$ and $(e_x, e_y)$ is the Cartesian basis of $\mathbb{R}^2$. The load term $f$, which is computed accordingly, is $f(x, y) = -a(\lambda + 3\mu)(e_x + e_y)$, where $\lambda$ and $\mu$ are the Lamé coefficients. The corresponding nonhomogeneous Dirichlet boundary condition is enforced on the whole boundary. Convergence results are reported in Table 2 showing that the energy error converges to first-order with the mesh size and the $L^2$-error to second-order.

4 | QUASISTATIC ELASTOPLASTICITY

In this section, we present the quasistatic elastoplasticity problem, its DEM discretization, and we perform numerical tests to assess the methodology.

4.1 | Governing equations

The quasistatic elastoplastic problem is a simplified formulation of (9) where the inertia term in the mass bilinear form is negligible and where the time derivatives are substituted by discrete increments. Thus, we consider a sequence of loads $l^n \in V^n_0$ for all $n = 1, \ldots, N$, and we consider the following sequence of nonlinear problems where $(u^n, \varepsilon^n, p^n, p^n) \in V_D \times Q_0 \times P$ for all $n = 1, \ldots, N$:

$$
\begin{aligned}
\begin{array}{ll}
a(\varepsilon^n_0; u^n, \bar{v}) = l^n(\bar{v}), \\
(\varepsilon^n_0, p^n, C^n_\text{ep}, \sigma^n) = \text{PLAS_IMP}(\varepsilon_0^{n-1}, p^{n-1}, \varepsilon^{n-1}, \varepsilon^n), & \forall \bar{v} \in V_0, \\
in \Omega,
\end{array}
\end{aligned}
$$

(39)

where $\varepsilon^{n-1} = \varepsilon(u^{n-1})$, $\varepsilon^n = \varepsilon(u^n)$, and where variables with a superscript $n-1$ come from the solution of the quasistatic problem (39) at the previous load increment or from a prescribed initial condition if $n=1$. Given a quadruple $(\varepsilon_0^n, p^n, C^n_\text{ep}, \sigma^n)$, the procedure PLAS_IMP returns a quadruple $(\varepsilon_0^n, p^n, C^n_\text{ep}, \sigma^n)$ such that

$$
\begin{aligned}
\begin{array}{ll}
\lambda^{\text{new}} \geq 0, & \varphi(\sigma^{\text{new}}, p^{\text{new}}) \leq 0, \\
\lambda^{\text{new}} \varphi(\sigma^{\text{new}}, p^{\text{new}}) = 0, & \delta p := p^n - p^{\text{old}} = \lambda^{\text{new}}, \\
\delta \varepsilon_p := \varepsilon^{\text{new}} - \varepsilon^{\text{old}} = \lambda^{\text{new}} \frac{d \varphi}{d \varepsilon}(\sigma^{\text{new}}),
\end{array}
\end{aligned}
$$

(40)
FIGURE 4  Choice of penalty factor: Left: Von Mises equivalent stress. Right: Trace of the stress tensor. First row: DEM with $\beta = 1$. Second row: DEM with $\beta = 0.1$. Third row: DEM with $\beta = 0.01$. Fourth row: Penalized Crouzeix-Raviart FE with $\beta = 1$ (reference). DEM, discrete element methods
Moreover, $\sigma^{new} = C : (\varepsilon^{new} - \varepsilon^p_{old})$ is the new stress tensor, and $C^{new}_{ep}$ is the consistent elastoplastic modulus$^{23}$ such that

$$\sigma^{new} = \sigma^{old} + C^{new}_{ep} : \delta \varepsilon, \quad \delta \varepsilon := \varepsilon^{new} - \varepsilon^{old}, \quad \sigma^{old} := C : (\varepsilon^{old} - \varepsilon^p_{old}).$$

(41)

The consistent elastoplastic modulus is instrumental to solve (39) iteratively by using an implicit radial return mapping technique (close to Newton-Raphson iterations)$^{24}$ Starting from $k = 0$, we solve iteratively the linear problem in $u^{n,k} \in V_D$ such that

$$\begin{cases}
(\nabla_{\varepsilon} u^{n,k}, \varepsilon(\nabla_{\varepsilon} u^{n,k+1}), \varepsilon(\nabla_{\varepsilon} v))_Q = r^{n,k}(\varepsilon(\nabla_{\varepsilon} v))_Q := l'(\varepsilon) - (\sigma^{n,k}, \varepsilon(\nabla_{\varepsilon} v))_Q, \\
(\varepsilon^p_{n,k}, p^{n,k}, C^{n,k}, \sigma^{n,k}) = \text{PLAS}_\text{IMP}(\varepsilon^p_{n-1}, p^{n-1}, \varepsilon^{n-1}, \varepsilon^{n,k}), \quad \forall \varepsilon \in \Omega,
\end{cases}$$

(42)

where the state for $k = 0$ comes from the previous loading step or the initial condition. Convergence of the iterative process in $k$ is reached when the norm of the residual $r^{n,k}$ is small enough.

### 4.2 | DEM space discretization

Using the DEM space discretization, the sequence of quasistatic problems (39) amounts to seeking a discrete triple $(u^n_h, \varepsilon^n_{p,c}, p^n_c) \in V_{hD} \times Q_h \times P_h$ for all $n = 1, \ldots, N$, solving the following nonlinear problem:

$$\begin{align*}
& a_h(\varepsilon^n_{p,c}; u^n_h, \varepsilon_h) = l^n_h(\varepsilon_h), \quad \forall \varepsilon_h \in V_{h0}, \\
& (\varepsilon^n_{p,c}, p^n_c, C^{n}_{ep,c}, \sigma^{n}_c) = \text{PLAS}_\text{IMP}(\varepsilon^{n-1}_{p,c}, p^{n-1}_c, \varepsilon^{n-1}_c, \varepsilon^n_c), \quad \forall c \in C,
\end{align*}$$

(43)

where $l^n_h$ represents a suitable discretization of the load linear form $l^n$. Using the radial return mapping technique as in (42) and starting from $k=0$, we solve iteratively the linear problem in $u^{n,k} \in V_{hD}$ such that

$$\begin{align*}
& \sum_{c \in C} |c|(\nabla_{\varepsilon} C^{n,k}_{ep,c} : \varepsilon_c(R(u^{n,k+1}_h))) : \varepsilon_c(R(\nabla_{\varepsilon} \varepsilon_h)) = r^{n,k}_c(\nabla_{\varepsilon} \varepsilon_h), \quad \forall \varepsilon_h \in V_{h0}, \\
& (\varepsilon^{n,k}_c, p^{n,k}_c, C^{n,k}_{ep,c}, \sigma^{n,k}_c) = \text{PLAS}_\text{IMP}(\varepsilon^{n-1}_{p,c}, p^{n-1}_c, \varepsilon^{n-1}_c, \varepsilon^n_c), \quad \forall c \in C,
\end{align*}$$

(44)

with the residual $r^{n,k}_c(\nabla_{\varepsilon} \varepsilon_h) := l^n(\nabla_{\varepsilon} \varepsilon_h) - \sum_{c \in C} |c|\sigma^{n,k}_c : \varepsilon_c(R(\nabla_{\varepsilon} \varepsilon_h))$, and where the discrete state for $k = 0$ comes from the previous loading step or by interpolating the values of the initial condition at the cell barycenters and the boundary vertices. Convergence of the iterative process in $k$ is reached when the norm of the residual $r^{n,k}_c$ is small enough (we use a scaled Euclidean norm).

### 4.3 | Numerical tests

This section contains two 3D tests, a beam in quasistatic flexion and a beam in quasistatic torsion, and a 2D test case on the swelling of an infinite cylinder with internal pressure.
4.3.1 | Beam in quasistatic traction

A beam of square section $S = 0.016m^2$ and $L = 1m$ is stretched by a displacement $u_D(t)$ imposed at its right extremity, whereas the normal displacement and the tangential component of the normal stress are null at the left extremity. An homogeneous Neumann condition ($\sigma \cdot n = 0$) is enforced on the four remaining sides of the beam. Figure 5 shows a sketch of the problem setup. The Young modulus is $E = 70 \cdot 10^3 Pa$ and the Poisson ratio $\nu = 0.3$. The yield stress is $\sigma_0 = 250Pa$, and the material is supposed to be elastoplastic with linear kinematic hardening. Specifically the tangent plastic modulus is set to $E_t = \frac{1}{5}E$, so that we have $R(p) = Hp$ with $H = \frac{E E_t}{E - E_t}$. The imposed displacement is linearly increased in 20 loading steps from 0 to $2\delta_y$, where $\delta_y = \frac{\sigma_0}{E}L$ is the yield displacement. For this test case the analytical solution is available.

Figure 6 shows the stress-strain response curve, showing perfect agreement with the analytical solution using a mesh of size $h = 0.2m$. Note that in this test case, the stress tensor is constant in the beam.

4.3.2 | Beam in quasistatic torsion

A beam of length $L = 0.2m$ with a circular section of radius $R = 0.05m$ is subjected to torsion at one of its extremities. The Young modulus is $E = 70 \cdot 10^3 Pa$ and the Poisson ratio $\nu = 0.3$. The yield stress is $\sigma_0 = 250Pa$, and the material is supposed to be perfectly plastic so that $R(p) = 0$. The beam is clamped at one of its extremities, a torsion angle $\alpha(t)$ is imposed at the other extremity, and the rest of the boundary of the beam is stress free ($\sigma \cdot n = 0$). Figure 7 presents the problem setup. The torsion angle $\alpha(t)$ is increased linearly in 20 loading steps from 0 to $\alpha_{\text{max}} = 2\alpha_y$, where $\alpha_y = \frac{\sigma_0 L}{\mu R \sqrt{3}}$ is the yield angle and $\mu$ is the second Lamé coefficient. An analytical solution is available in the cylindrical frame $(r, \theta, z)$: the displacement field is $u(r, z, t) = \alpha(t) r \frac{L}{L} e_\theta$, and the stress field is $\sigma(r, t) = \tau(r, t)(e_\theta \otimes e_z + e_z \otimes e_\theta)$, where

$$
\tau(r, t) := \begin{cases} 
\mu \alpha(t) \frac{L}{L}, & 0 \leq r \leq R \frac{\alpha_y}{\alpha(t)} \\
\sigma_0, & R \frac{\alpha_y}{\alpha(t)} \leq r \leq R.
\end{cases}
$$
**FIGURE 7** Beam in quasistatic torsion: Problem setup

**FIGURE 8** Beam in quasistatic torsion. Left: torque-angle response curve for the reference solution and the DEM solution on various meshes. Right: difference between the reference solution and the DEM solution on various meshes. DEM, discrete element methods

Table 3 reports the maximum $L^2$-error on the displacement (evaluated as in Section 3.5) over the simulation interval and the energy error (including the energy of the penalty terms). The errors are evaluated as described in Section 3.5. First-order convergence in the energy norm is observed, as expected. However, full second-order convergence in $L^2$ norm does not seem satisfied (although the convergence order is still above 1.77). This can be due to the fact that in perfect plasticity $u \notin H^2(\Omega)$ which is a required hypothesis to obtain full second-order convergence.

Figure 8 presents the torque-angle response curve for the reference solution and the DEM solution on various meshes, showing good agreement and the convergence of the DEM predictions as the mesh is refined.
4.3.3 Inner swelling of an infinite cylinder

This test case consists in the inner swelling of an infinite cylinder. The inner radius is \( R_i = 1 \) m and the outer radius is \( R_o = 1.3 \) m. Owing to the symmetries, the computation is carried out on a quarter of a planar section of the cylinder with a plane strain formulation. A sketch of the problem setup is presented in Figure 9. On the lateral sides of the quarter of cylinder, a null normal displacement and a null tangential component of the normal stress are enforced. The outer side of the cylinder is stress free (\( \sigma \cdot n = 0 \)), and the inner pressure \( \sigma \) imposed on the inner side is linearly increased from 0 to \( p_{max} = \frac{2}{\sqrt{3}} \sigma_0 \ln \left( \frac{R_o}{R_i} \right) \), where \( \sigma_0 = 250 \text{N.m}^{-2} \) is the initial yield stress. The Young modulus and the tangent plastic modulus are set to \( E = 70 \cdot 10^3 \text{Pa} \) and \( E_t = \frac{1}{100} E \).

Table 4 reports the \( L_2 \)-error on the displacement (evaluated as in Section 3.5) and on the cumulated plastic strain. The reference solution is computed on the finest mesh and is based on \( P^2 \)-Lagrange FE using the implementation available in Reference 25. The results in Table 4 show that the method converges at order two in the \( L_2 \)-norm and at order one in the energy norm.

5 SPACE-TIME FULLY DISCRETE ELASTOPLASTICITY

In this section, we consider the dynamic elastoplasticity equations from Section 2. The time discretization is performed by means of an explicit, pseudoenergy conserving, time-integration scheme recently introduced in Reference 15. The space discretization is achieved by means of the DEM scheme discussed in Sections 3 and 4. The main difference with Section 4.3 is that no iterative procedure is necessary in this section. 3D test cases are presented to assess the proposed methodology.

5.1 Time semidiscretization of dynamic elastoplasticity

For simplicity we consider in this section only the time semidiscretization of the dynamic elastoplasticity Equation (9). We deal with the space-time fully discrete setting in the following section. The time-integration scheme is a two-step method of order two which ensures a discrete pseudoenergy conservation, if the integration of forces is exact, even for nonlinear systems. Symmetric Gaussian quadratures of the forces can be used in practice as long as they are of order at least two. The time interval \((0, T)\) is discretized using the time nodes \( 0 = t_0 < \cdots < t_n < \cdots < t_N = T \), and for simplicity we consider a constant time step \( \Delta t \). We define the half-time nodes \( t_{n+\frac{1}{2}} = \frac{1}{2} (t_n + t_{n+1}) \) for all \( n = 0, \ldots, N \). The time step is limited by a CFL condition which we specify in the fully discrete setting in the following section.
The key idea in the scheme\(^{15}\) is to approximate the displacement field at the time nodes by means of functions \(u^n\), for all \(n = 0, \ldots, N\), with \(u^0\) specified by the initial condition on the displacement, and the velocity field at the half-time nodes by means of functions \(v^{n+\frac{1}{2}}\), for all \(n = 0, \ldots, N\), with \(v^0\) specified by the initial condition on the velocity. For all \(n = 0, \ldots, N\), given \(u^n\) and \(v^{n+\frac{1}{2}}\), the scheme performs two substeps: (i) A time-dependent displacement field is predicted on the time interval \([t_n, t_{n+1}]\) using the free-flight expression \(\bar{u}(t) = u^* + (t - t_n)v^{n+\frac{1}{2}}\) for all \(t \in [t_n, t_{n+1}]\); (ii) The velocity field \(v^{n+\frac{1}{2}}\) is predicted by means of a quadrature on the time-integration of the forces in the time interval \([t_n, t_{n+1}]\). Let \(\{\ell_{h,k}\}_{k \in \mathcal{K}}\) and \(\{\omega_{h,k}\}_{k \in \mathcal{K}}\) be the nodes and the weights for the quadrature in the time interval \([t_n, t_{n+1}]\). We then set

\[
\begin{align*}
\ell_{h,k} & = u^n_k + (t_{n,k} - t_n)v^{n+\frac{1}{2}}, \quad \forall k \in \mathcal{K}, \\
\ell_{p,c}^{n,k} & = \text{PLAS\_EXP}(\ell_{p,c}^{n-1,k}, \ell_{c}^{n,k}), \quad \forall k \in \mathcal{K}, \\
\frac{1}{2}m(v^{n+\frac{1}{2}} - v^{n-\frac{1}{2}}, \tilde{v}) & = \sum_{k \in \mathcal{K}} \omega_{h,k} \left(l(t_{n,k}, \tilde{v}) - a(\ell_{p,c}^{n,k}, u^{n,k}, \tilde{v})\right), \quad \forall \tilde{v} \in V_h,
\end{align*}
\]

where \(\ell_{c}^{n,k} = \ell_{c}(R(u^{n,k}))\). Moreover, \(m_h\) and \(l_h\) are, respectively, the discrete mass bilinear form and the discrete load linear form. For the first Gauss node \(k = 1\), the first two arguments in \text{PLAS\_EXP} come from the previous time step or the initial condition. The initial displacement \(u^0_h\) and the initial velocity \(v^{\frac{1}{2}}_h\) are evaluated by using the values of the prescribed initial displacement \(u_0\) and the prescribed initial velocity \(v_0\) at the cell barycenters and the boundary vertices.

The time step is restricted by the following CFL stability condition:

\[
\Delta t < 2 \sqrt{\frac{\mu_{\text{min}}}{\lambda_{\text{max}}}}
\]
where $\mu_{\text{min}}$ is the smallest entry of the diagonal mass matrix associated with the discrete mass bilinear form $m_h(\cdot, \cdot)$ and $\lambda_{\text{max}}$ is the largest eigenvalue of the stiffness matrix associated the discrete stiffness bilinear form $a_h(0; \cdot, \cdot)$ (i.e., this maximal eigenvalue is computed in the worst-case scenario when there is no plasticity). The CFL condition (48) guarantees the stability of the time-integration scheme in the linear case, that is, when there is no plasticity. We expect that this condition is still reasonable in the nonlinear case since plasticity does not increase the stiffness of the material.

Finally, let us write the discrete equivalent of the energy conservation property (11). Define the discrete elastic energy at $t_{n+1}$ as

$$E_{\text{elas},h}^{n+1} := \frac{1}{2} \sum_{c \in C} |c| \sigma_{c}^{n+1} : \mathbb{C}^{-1} : \sigma_{c}^{n+1},$$

with $\sigma_{c}^{n+1} := \mathbb{C} : (\varepsilon_{c}(R(u^{n+1}_h)) - \varepsilon_{p}^{n+1}),$ for all $c \in C.$ The discrete kinetic energy at $t_{n+1}$ is defined by

$$E_{\text{kin},h}^{n+1} := \frac{1}{2} m_h(v^{n+3/2}_h, v^{n+1/2}_h),$$

the discrete plastic dissipation at $t_{n+1}$ is defined by

$$E_{\text{plas},h}^{n+1} := \sum_{c \in C} |c| (\sigma_{0} p_{c}^{n+1} + a_{p}(p_{c}^{n+1})),$$

and finally the work of external loads at $t_{n+1}$ is defined by

$$E_{\text{ext},h}^{n+1} := \sum_{m=0}^{n} l_{h}(t_{m+1}; v^{m+1/2}_h) \Delta t.$$

Then assuming a homogeneous Dirichlet condition for simplicity, we have the following energy balance equation:

$$E_{\text{elas},h}^{n+1} + E_{\text{kin},h}^{n+1} + E_{\text{plas},h}^{n+1} = E_{\text{ext},h}^{n+1} + E_{\text{elas},h}^{0} + E_{\text{kin},h}^{0} + \mathcal{O}(\Delta t^{2}),$$

(49)

where the term $\mathcal{O}(\Delta t^{2})$ results from the use of quadratures to compute the integral of forces (recall that $E_{\text{plas},h}^{0} = 0$ in our setting). The interested reader is referred to Reference 15 for further details on the effect of quadratures on the conservation properties of the integration method.

### 5.3 Numerical tests

This section contains two 3D test cases: a beam in dynamic flexion and a beam in dynamic torsion. We use the midpoint quadrature for the integration of the forces in each time step within the time-integration scheme. We refer the reader to Reference 15 for a study of the influence of the quadrature on the scheme accuracy for various nonlinear problems with Hamiltonian dynamics.

Although the material parameters are indicated below using physical units, they are best interpreted in terms of characteristic times. For instance, considering a one-dimensional domain of length $L$, the characteristic time of the numerical experiments is $T_{\text{ref}} := L \sqrt{\frac{\rho}{E}}$. The CFL condition (48) restricts the time-step as $\Delta t < 2 \sqrt{\frac{\mu_{\text{min}} E}{\lambda_{\text{max}} \rho}}$. Thus, one has

$$\frac{\Delta t}{T_{\text{ref}}} < 2 \sqrt{\frac{\mu_{\text{min}} E}{\lambda_{\text{max}} \rho}}.$$

Since the ratio $\frac{E}{\lambda_{\text{max}}}$ is independent of $E$, the same conclusion holds for $\frac{\Delta t}{T_{\text{ref}}}$. Therefore, we will report this time ratio in the computations.
5.3.1  |  Beam in dynamic flexion

This test case consists in computing the oscillations of an elastic and linearly isotropic plastic beam of length \( L = 1 \text{m} \) with a rectangular section of \( 0.04 \times 0.1 \text{m}^2 \). The simulation time is \( T = 2.5 \text{s} \). The beam is clamped at one end, it is loaded by a uniform vertical traction \( g(t) \) at the other end, and the four remaining lateral faces are stress free (\( \sigma \cdot n = 0 \)). The load term \( g(t) \) is defined as

\[
g(t) := \begin{cases} 
-\frac{5}{4} t^4 & \text{for } 0 \leq t \leq \frac{4}{5}, \\
0 & \text{for } \frac{4}{5} \leq t \leq T.
\end{cases}
\]

Figure 10 displays the problem setup. The material parameters are \( E = 10^3 \text{Pa} \) for the Young modulus, \( \nu = 0.3 \) for the Poisson ratio, \( \rho = 1 \text{kg} \cdot \text{m}^{-3} \) for the density, \( \sigma_0 = 25 \text{Pa} \) for the yield stress, and \( E_t = \frac{1}{100} E \) for the tangent plastic modulus. The present 3D implementation used as a starting point, where \( P^1 \)-Lagrange FE and an implicit time-integration scheme are considered for a purely elastic material.

The proposed DEM is compared with penalized Crouzeix-Raviart FE. This method is chosen as reference since it is known to be robust in the incompressible limit as \( \nu \to 0.5 \). The penalty parameter is chosen as \( \eta = \beta \mu \) with \( \beta = 0.5 \). The reference computation is performed using 14,376 vector-valued dofs and a time-step \( \Delta t = 20 \mu\text{s} \). Two computations are performed with the proposed DEM. The first uses a coarse mesh containing 4,668 vector-valued dofs and a time-step \( \Delta t = 1.4 \mu\text{s} \), which is stable for the explicit integration. The second uses a fine mesh containing 13,302 vector-valued dofs and a time-step \( \Delta t = 1.1 \mu\text{s} \), also stable for the explicit integration. Thus, one has: \( 4.4 \cdot 10^{-7} \leq \Delta t \leq 8.0 \cdot 10^{-6} \). The penalty parameter for both computations is similar to the reference computation with \( \beta = 0.5 \). As already mentioned, we used a midpoint quadrature of the forces. Higher order symmetric quadratures have been found to give overlapping results with respect to the midpoint quadrature. In all the computations, the time-discretization error is actually smaller than the space-discretization error, but larger time-steps cannot be considered owing to the CFL restriction.

The displacement and the velocity at the center of the loaded tip of the beam are compared in Figure 11. We notice the excellent agreement between the DEM prediction on the fine mesh and the reference computation. Figure 12 shows the balance of energies for the reference computation and the fine DEM computation. One can first notice that the total energy for both DEM and Crouzeix-Raviart space semidiscretizations is well preserved by the time-integrator since the total mechanical energy (kinetic energy, elastic energy and plastic dissipation) and the work of the external load are perfectly balanced at all times. We also notice that the amount of plastic dissipation is rather significant at the end of the simulation.

Figure 13 presents some further results of the DEM computations on the fine mesh so as to visualize at three different times during the simulation the spatial localization of the von Mises equivalent stress, the cumulated plastic strain, and the trace of the stress tensor. One can see that the plastic strain is concentrated close to the clamped tip of the beam, where the material undergoes the greatest stresses. The method does not exhibit any locking due to plastic incompressibility as indicated by the smooth behavior of the trace of the stress tensor.

5.3.2  |  Beam in dynamic torsion

The setting is similar to the quasistatic torsion test case presented in Section 4.3.2. The two differences are the material parameters and the plastic law which are similar to Section 5.3.1, and the boundary conditions on one side of the beam. Figure 14 shows the problem setup. On one of its extremities the beam is clamped, and on the other extremity the following
normal stress is imposed:

\[
g(t) = \mu \alpha(t) \frac{r}{L} e_\theta,
\]

where \( r \) and \( e_\theta \) are defined in Section 4.3.2. The angle \( \alpha(t) \) is increased from 0 at \( t = 0 \) to \( 5\alpha_y \) at \( t = T = 0.5 \text{s} \), where \( \alpha_y \) is the yield angle defined in Section 4.3.2. The plastic parameters are the same as those in Section 5.3.1. Three different space discretizations are considered for this test case: \( P^1 \)-Lagrange FE, penalized Crouzeix-Raviart FE, and the proposed DEM. The Crouzeix-Raviart computations are used as reference since the method is known to be robust with respect to the incompressible limit. The Lagrange FE computations are used to illustrate their inability to deal with large plastic (deviatoric) strains. The goal of this test case is to show the ability of the proposed DEM to deal with deviatoric plasticity. The computations are not performed on the same meshes but rather with meshes leading to a similar number of dofs so as to give comparable results for DEM and Lagrange FE, whereas the meshes used with penalized Crouzeix-Raviart FE lead to twice as many dofs since they are employed to obtain a reference solution. The number of dofs and the time-steps used in the computations are presented in Table 5.
One thus has: $8.4 \cdot 10^{-7} \leq \frac{\Delta t}{T_{\text{ref}}} \leq 8.2 \cdot 10^{-6}$. All the reported time-steps are compatible with the CFL restriction. In addition, for all computations, we have verified that the time discretization error is negligible with respect to the space discretization error. The time-integration scheme\cite{15} is used with a midpoint quadrature of the forces for the coarse computations and with a Gauss-Legendre quadrature of the forces of order 5 for the fine computations. For details on the effect of the quadrature rule, see Reference\cite{15}.

The comparison between the methods is performed by considering the displacement and the velocity of the point of coordinates $(0.9R, 0, \frac{1}{6}L)$ over the simulation time $T$. The results are reported in Figure\ref{fig:results}.

The angular velocity plot indicates for times $t \leq 0.2s$ the presence of elastic waves with a small magnitude travelling through the beam. The wave of larger amplitude arriving afterward is a plastic wave whose velocity is 10 times smaller than the elastic waves since $E_r = \frac{E}{100}$. We notice that the value for the simulation time is too long for the simulation to remain physically relevant within the small strain assumption owing to the large value reached by the angular displacement of the reference point. However, this setting allows us to reach substantial amounts of plastic dissipation and thereby to probe the robustness of the space semidiscretization methods with respect to incompressibility. Recall that the remanent plastic strain tensor is trace-free, so that the stress tensor is nearly deviatoric in the entire beam at the end of the simulation. Such a situation is challenging for the $P^1$-Lagrange FEM since this method is known to lock in the incompressible limit.
To highlight the volumetric locking incurred by Lagrange FE, Figure 16 displays at the time $t = \frac{1}{2}T$ the trace of the stress tensor predicted by Lagrange FE (fine mesh) and penalized Crouzeix-Raviart FE (coarse mesh), for a similar number of dofs.

For Lagrange FE, significant oscillations are visible in the whole beam (the amplitude of these oscillations is about 10 times the maximal value of the von Mises equivalent stress). In addition, the amplitudes of the oscillations of the trace tensor are about four times larger than for penalized Crouzeix-Raviart FE. Figure 17 reports the energies on the fine meshes for the DEM, Lagrange FE, and penalized Crouzeix-Raviart FE. First, we notice as in the previous test case the perfect balance of the work of external loads with the different components of the mechanical energy. The orders of magnitude of the energies and plastic dissipations are similar for the three methods. However, a significant discrepancy in the plastic dissipation can be observed for Lagrange FE with respect to penalized Crouzeix-Raviart FE and DEM which both give a plastic dissipation similar to the reference computation.

Figure 18 presents some further results of the DEM computations on the fine mesh so as to visualize at three different times during the simulation the spatial localization of the von Mises equivalent stress, the cumulated plastic strain, and the trace of the stress tensor. We can see in the first row that the von Mises stress is nonzero in the entire beam and thus the elastic waves have already travelled through the entire beam whereas the cumulative plastic strain is still zero and thus no plastic flow has occurred. In the second row, we can see that a plastic wave has started to propagate from one end of the beam. In the last row, we see that the plastic wave has reached the other side of the beam at the end of the simulation. In addition, regarding the robustness with respect to $\nu \to 0.5$, the magnitude of the oscillations of the trace of the stress tensor is similar to penalized Crouzeix-Raviart FE. Indeed for the DEM, the extreme values of the trace of the stress tensor are $-3 \times 10^2 \text{Pa}$ and $3 \times 10^2 \text{Pa}$ at $t = T$ and $-9 \times 10^2 \text{Pa}$ and $7 \times 10^2 \text{Pa}$ at $t = T$ whereas for penalized Crouzeix-Raviart FE the extremes values are $-2 \times 10^2 \text{Pa}$ and $2 \times 10^2 \text{Pa}$ at $t = \frac{T}{2}$ and $-6 \times 10^2 \text{Pa}$ and $6 \times 10^2 \text{Pa}$ at $t = T$. Comparatively, for the

| Method         | DEM    | Lagrange FE | penalized CR FE |
|----------------|--------|-------------|-----------------|
| Computation    | coarse | fine        | coarse          | fine            | very fine       |
| Vectorial dofs | 6978   | 14438       | 6584            | 12 853          | 13 052          | 27 711          |

\( P^1 \)-Lagrange FE computations, the extreme values of the trace of the stress tensor are \(-8 \times 10^2 \text{Pa}\) and \(9 \times 10^2 \text{Pa}\) for \( t = \frac{T}{2} \) and \(-2 \times 10^3 \text{Pa}\) and \(2 \times 10^3 \text{Pa}\) for \( t = T \).

### 6 | CONCLUSION

We have presented a new DEM which is a variational discretization of a Cauchy continuum and which only requires continuum macroscopic parameters as the Young modulus and the Poisson ratio for its implementation. The displacement degrees of freedom are attached to the barycenters of the mesh cells and to the boundary vertices. The key idea is to reconstruct displacements on the mesh facets and then to use a discrete Stokes formula to devise a piecewise constant gradient and linearized strain reconstructions. A simple geometric preprocessing has been devised to ensure that for almost all the mesh facets, the reconstruction is based on an interpolation (rather than extrapolation) formula and we have shown by numerical experiments that this choice can produce highly beneficial effects in terms of the largest eigenvalue of the stiffness matrix, and thus on the time step restriction within explicit time-marching schemes. Moreover, in the case of elastoplastic behavior, the internal variables for plasticity are piecewise-constant in the mesh cells. The scheme has been tested on quasistatic and dynamic test cases using a second-order, explicit, energy-conserving time-marching scheme. Future work can include adapting the present framework to dynamic cracking and fragmentation as well as to Cosserat continua. An extension to large strain solid dynamics could also be performed by working in the reference configuration.
ACKNOWLEDGEMENTS
