Recent observations suggest that a large fraction of the energy density of the universe has negative pressure. One explanation is vacuum energy density; another is quintessence in the form of a scalar field slowly evolving down a potential. In either case, a key problem is to explain why the energy density nearly coincides with the matter density today. The densities decrease at different rates as the universe expands, so coincidence today appears to require that their ratio be set to a specific, infinitesimal value in the early universe. In this paper, we introduce the notion of a “tracker field,” a form of quintessence, and show how it may explain the coincidence, adding new motivation for the quintessence scenario.

A number of recent observations suggest that $\Omega_m$, the ratio of the (baryonic plus dark) matter density to the critical density, is significantly less than unity. Either the universe is open, or there is some additional energy density $\rho$ sufficient to reach $\Omega_{\text{total}} = 1$, as predicted by inflation. Measurements of the cosmic microwave background, the mass power spectrum, and, most explicitly, the luminosity-red shift relation observed for Type Ia supernovae, all suggest that the missing energy should possess negative pressure ($p$) and equation-of-state ($w = p/\rho$). One candidate for the missing energy is vacuum energy density or cosmological constant, $\Lambda$ for which $w = -1$. The resulting cosmological model, $\Lambda$CDM, consists of a mixture of vacuum energy and cold dark matter. Another possibility is QCDM cosmologies based on a mixture of cold dark matter and quintessence ($-1 < w < 0$), a slowly-varying, spatially inhomogeneous component. An example of quintessence is the energy associated with a scalar field ($Q$) slowly evolving down its potential $V(Q)$. Slow evolution is needed to obtain negative pressure, $p = \frac{1}{2}Q^2 - V(Q)$, so that the kinetic energy density is less than the potential energy density.

Two difficulties arise from all of these scenarios. The first is the fine-tuning problem: Why is the missing energy density today so small compared to typical particle physics scales? If $\Omega_m \sim 0.3$ today the missing energy density is of order $10^{-47}$ GeV$^4$, which appears to require the introduction of new mass scale 14 or so orders of magnitude smaller than the electroweak scale. A second difficulty is the “cosmic coincidence” problem. Since the missing energy density and the matter density decrease at different rates as the universe expands, it appears that their ratio must be set to a specific, infinitesimal value in the very early universe in order for the two densities to nearly coincide today, some 15 billion years later.

What seems most ideal is a model in which the energy density in the $Q$-component is comparable to the radiation density (to within a few order of magnitude) at the end of inflation, say. If there were some rough equipartition of energy following reheating among several thousands of degrees of freedom, one might expect the energy density of the $Q$-component to be two or so orders of magnitude smaller than the total radiation density. One would want that the energy density of the $Q$-component somehow tracks below the background density for most of the history of the universe, and, then, only recently, grows to dominate the energy density and drive it into a period of accelerated expansion. The models we present will do all this and more even though there is only one adjustable parameter. The models are extremely insensitive to initial conditions — variations in the initial ratio of the $Q$-energy density to the matter density by nearly 100 orders of magnitude do not affect the cosmic history. The models are in excellent agreement with current measurements of the cosmic microwave background, large scale structure, and cosmic acceleration. We also find that the models predict a relation between $\Omega_m$ and the acceleration of the universe. These properties suggest a new perspective for the quintessence models, perhaps placing them on equal footing with the more conventional $\Lambda$ models.

The models considered in this Letter are based on the notion of “tracker fields,” a form of quintessence in which the tracker field $Q$ rolls down a potential $V(Q)$ according to an attractor-like solution to the equations-of-motion. The tracker solution is an attractor in the sense that a very wide range of initial conditions for $Q$ and $\dot{Q}$ rapidly approach a common evolutionary track, so that the cosmology is insensitive to the initial conditions. Tracking has an advantage similar to inflation in that a wide range of initial conditions is funneled into the same final condition. This contrasts with most quintessence potentials studied previously in the literature which require very fine adjustment of the initial value of $Q$ (as well as parameters in the potential) to obtain a suitable cosmology. We introduce the term “tracker” because there is a subtle but important difference from attractor solutions in dynamical systems. Unlike a standard attractor, the tracker solution is not a fixed point (in the sense of a fixed point solution of a system of autonomous differential equations.
of motion); the ratio of the $Q$-energy to the background matter or radiation density changes steadily as $Q$ proceeds down its track. This is desirable because one is interested in having the $Q$-energy ultimately overcome the background density and drive the universe towards an accelerating phase. This contrasts with the “self-adjusting” background density and drive the universe towards an accelerating phase. This contrasts with the “self-adjusting” background density and drive the universe towards an accelerating phase. This contrasts with the “self-adjusting” background density and drive the universe towards an accelerating phase. This contrasts with the “self-adjusting” background density and drive the universe towards an accelerating phase. This contrasts with the “self-adjusting” background density and drive the universe towards an accelerating phase. This contrasts with the “self-adjusting” background density and drive the universe towards an accelerating phase.

The tracker field $Q$ satisfies the equation-of-motion:

$$\ddot{Q} + 3H\dot{Q} + V'(Q) = 0$$

where $V'(Q)$ is the derivative of $V$ with respect to $Q$ and $H$ is the Hubble parameter. For the inverse power-law potential, $Q$ has a tracker solution which maintains the condition:

$$V'' = (9/2)(1-w_Q^2)((\alpha + 1)/\alpha)H^2.$$

The condition that $\rho_Q$ is beginning to dominate today means that $Q$ must be $\mathcal{O}(M_p)$ today since $V'' \approx \rho_Q/Q^2$ and $H^2 \approx \rho_Q/M_p^2$.

The one free parameter, $M$, is determined by the observational constraint, $\Omega_Q \approx 0.7$ today. Here is where the fine-tuning issue must be considered. To have $\Omega_Q \approx 0.7$ today requires $V(Q \approx M_p) \approx \rho_m$, where $\rho_m \approx 10^{-47} \text{ GeV}^4$ is the current matter density; this imposes the constraint $M \approx (\rho_m M_p^4)^{1/(\alpha+4)}$. For low values of $\alpha$ or for the exponential potential, this forces $M$ to be a tiny mass as low as 1 meV for the exponential case. However, we note that $M > 1 \text{ GeV}^4$ — comparable to particle physics scales — is possible for $\alpha \geq 2$. Hence, while this is not our real aim, it is interesting to note that the tracker solution does not require the introduction of a new mass hierarchy in fundamental parameters.

To address the coincidence problem — removing the need to tune initial conditions in order for the matter and missing energy densities to nearly coincide today — our proposal relies on the tracking behavior of $Q$ in a background of standard cosmology. Let us first consider $V(Q) = M^{4+\alpha}Q^{-\alpha}$ for $\alpha \geq 1$. For any fixed $M$, the tracker solution is determined by Eq. (\ref{eq:tracker}). We shall call the energy density in the $Q$-field as a function of $z$ along the tracker solution $\bar{\rho}_Q(z)$. If initial conditions are set at $z = z_i$, at the end of inflation, say, then one possibility is that the initial energy density in $Q$ is less than the attractor value, $\rho_Q(z_i) < \bar{\rho}_Q(z_i)$. In this case, the field remains frozen until $H^2$ decreases to the point where Eq. (\ref{eq:tracker}) is satisfied. See Figure 1. After that point, $Q$ begins rolling down the potential, maintaining the condition in Eq. (\ref{eq:tracker}) as it rolls along. A second possibility is that the initial energy density in $Q$ is greater than the tracker value but less than the background radiation density, $\bar{\rho}_Q(z_i) < \rho_Q(z_i) < \rho_B(z_i)$. This includes the case of equipartition after reheating. In this case $Q$ starts rolling down the potential immediately and so rapidly that its kinetic energy dominates over the potential energy density $V(Q)$. The kinetic energy density red shifts as $1/a^6$ and eventually $Q$ comes nearly to a stop at $Q \approx 0.5(\rho_Q(z)/\rho_B(z))^{1/2}M_p$. By this point, $Q$ has fallen below the tracker solution, $\bar{\rho}_Q$. Now, Q remains nearly frozen and $H$ decreases until Eq. (\ref{eq:tracker}) is satisfied.
Then, $Q$ tracks the same solution as before. Hence, any initial $\rho_Q$ less than the initial background radiation density, including equipartition initial conditions, leads to the same tracker solution and the same cosmology.

The only troublesome case is if $Q$ dominates over the background radiation density initially, $\rho_Q \gg \rho_B$. In this case, $Q$ grows to a value greater than $M_p$ before it slows down; this overshoots the tracker solution to such an extent that the tracker is not reached by the present epoch and $\rho_Q$ is insignificant today. On the other hand, the initial condition $\rho_Q \gg \rho_B$ seems unlikely.

For the pure inverse power-law potential, the energy density decays as a constant power of the scale factor $a$; i.e., $\rho_Q \propto a^{-3(1+w_Q)}$ and

$$w_Q \approx \frac{2w_B - 1}{1 + \frac{a}{2}},$$

where this approximation is valid so long as $\rho_B \gg \rho_Q$. The variable $w_B$ is the equation-of-state of the background: $w_B = 0$ in the matter-dominated epoch and $w_B = 1/3$ in the radiation-dominated epoch. That is, the $Q$-component acts as a fluid with constant equation-of-state, but its value of $w_Q$ depends both on its effective potential $V(Q)$ and on the background. The effect of the background is through the $3HQ$ in the equation-of-motion for $Q$, Eq. (4): when $w_B$ changes, $H$ also changes which, in turn, changes rate at which the tracker field evolves down the potential.

The second remarkable feature of the tracker solutions is that $w_Q$ automatically decreases to a negative value as the universe transforms from radiation- to matter-dominated, whether $w_Q$ is positive ($\alpha > 6$) or negative ($\alpha < 6$) in the radiation-dominated epoch. This means that $\rho_Q$ decreases at a slower rate than the matter density. Consequently, the matter-dominated era cannot last forever. Eventually, perhaps close to the present epoch, the $Q$-component overtakes the matter density.

The third remarkable feature is that, once the $Q$-component begins to dominate, its behavior changes again: the $Q$-field slows to nearly a stop causing the equation-of-state $w_Q$ to decrease towards -1. Hence, the universe begins a period of accelerated expansion.

If $\Omega_m \geq 0.2$ today, then the $Q$-component has dominated for only a short time and $w_Q$ has not had time to reach -1 today. For $\alpha > 1$, $w_Q$ is nearly 1/3 during the radiation epoch, nearly zero in the matter dominated epoch, and has fallen to a value $\gtrsim -1/3$ today. The predicted current value is larger than recent supernovae results suggest. As $\alpha$ is made smaller, $w_Q$ is smaller at each stage along the tracker solution, including today. For $\alpha \leq 6$, for example, we find $w_Q \gtrsim -0.8$ for $\Omega_m \geq 0.2$, in closer accord with recent supernovae results.

**FIG. 1.** The evolution of the energy densities for a quintessence component with $V(Q) = M^4[\exp(M_p/Q) - 1]$ potential. The solid line is where $\rho_Q$ is initially comparable to the radiation density and immediately evolves according to tracker solution. The dot-dashed curve is if, for some reason, $\rho_Q$ begins at a much smaller value. The field is frozen and $\rho_Q$ is constant until the dot-dashed curve runs into tracker solution, leading to the same cosmology today: $\Omega_m = 0.4$ and $w_Q = -0.65$.

![Figure 2](image2.png)

**FIG. 2.** $w_Q$ vs. $z$ for the model in Figure 1. During the radiation-dominated epoch (large $z$), $w_Q \approx 1/3$ and the $Q$-energy density tracks the radiation background. During the matter-dominated epoch, $w_Q$ becomes somewhat negative (dipping down to $w_Q \approx -0.2$ beginning at $z = 10^4$) until $\rho_Q$ overtakes the matter density; then, $w_Q$ plummets towards -1 and the universe begins to accelerate.

The exponential potential, $V(Q) = M^4[\exp(M_p/Q) - 1]$, is an example of combining inverse power-law models, which introduces yet another generic feature of tracking. The exponential potential can be expanded in inverse powers of $Q$, where the dominant power $\alpha$ varies from high values to low values as $Q$ evolves towards larger values, causing $w_Q$ to decrease as the universe ages. As a result, $\Omega_Q$ grows more rapidly as the universe ages, making it more likely that $\Omega_Q$ dominates later in the history of the universe rather than earlier. We use this model for the purposes of illustration. In Figure 1 we show the
evolution of $\rho_Q$ relative to the matter and radiation density. We show the case where $\rho_Q$ is comparable to the radiation density at the end of inflation (solid curve) and also the case where $\rho_Q$ is initially much smaller. The latter case produces precisely the same cosmology once the $Q$-field starts rolling. In Figures 2-4, we illustrate the evolution of $w_Q$, the comparison of the linear mass power spectrum to recent Automatic Plate Measuring (APM) large-scale structure survey results, and the cosmic microwave background temperature anisotropy power spectrum compared to recent data from the COBE, Big Plate and CAT experiments.

An important prediction to emerge from the tracker field models is a relation between $\Omega_m$ and $w_Q$ today (for fixed $h$). For any given potential, the prediction is precise: fixing $\Omega_m$ today also fixes the one free parameter, $M$. Consequently, $w_Q$ is determined, as well. Even without restricting to a particular potential, the trend is clear: smaller $\Omega_m$ means that the tracker field has been dominating longer and $w_Q$ is closer to -1 today. Given that $\Omega_m \geq 0.2$, we have found that it is not possible to obtain $w_Q < -0.8$ without adding artificial complications to the potential. The bound is very weakly $h$-dependent. This value is significantly different from $w = -1$ for a cosmological constant and one can hope to detect this difference.

One brief word should be added about the future of the universe: as $Q$ continues to evolve, it slows down and $w_Q$ approaches arbitrarily close to -1. So, the universe expands as if there is a fixed non-zero cosmological constant, even though the reality is that $Q$ is slowly oozing its way downhill.

We thank R. Caldwell and A. Liddle for useful conversations. This research was supported by the US Department of Energy grants DE-FG02-95ER40893 (Penn) and DE-FG02-91ER40671 (Princeton). We have modified the CMBFAST software routines for our computations.
