doi: 10.18176/archmeddeporte.00012

Objective: To evaluate the differences in quantitative ultrasound of the quadriceps in a sample of schoolchildren who practise different sports.

Material and method: A transversal, comparative and non-randomised study was carried out with an intentional sample of 184 schoolchildren, aged between 7 and 10 years. The sample was divided into three groups based on the sport practised: a) only soccer; b) volleyball, basketball, swimming, gymnastics and cheerleading; and c) no sport practised. The eco-intensity, thickness and pennation angle of some components of the quadriceps (rectus femoris, vastus lateralis and vastus intermedius) were measured using B-mode ultrasound imaging.

Results: There were significant differences between the 3 groups of children in the variables that measure the quality of the muscle: eco-intensity and fat percentage of the rectus femoris (p < 0.05), muscle thickness of the anterior (p< 0.05) and lateral (p< 0.01) vastus intermedius, and in the pennation angle of the rectus femoris (ARF) (p< 0.05) and of the vastus lateralis (AVL) (p< 0.01). Between groups b and c there were differences in the ARF in boys (p< 0.01) and in the AVL in girls (p< 0.05).

Conclusion: The way in which sport initiation is carried out in children between 7 and 10 years of age may cause differences in the quadriceps muscle, which can be demonstrated through the use of quantitative ultrasound. Moreover, such differences are related to the duration and frequency of the stimulus, which becomes a qualitative aspect to be considered when programming the training contents at these ages.

Key words: Child. Ultrasonography. Sports. Muscle development. Quadriceps muscle.

Summary

Resumen

Objetivo: Evaluar las diferencias en ecografía cuantitativa del cuádriceps en niños y niñas escolares practicantes de diferentes deportes.

Material y método: Se realizó un estudio transversal, comparativo y no aleatorizado. Se utilizó una muestra intencional compuesta por 184 niños escolares, entre 7 y 10 años. La muestra fue dividida en 3 grupos según la modalidad deportiva practicada: a) un grupo que solo practicaba fútbol; b) otro grupo donde practicaban voleibol, baloncesto, natación, gimnasia y cheerleading; y c) un grupo que no practicaban ninguna modalidad deportiva. La eco-intensidad, el espesor y el ángulo de penneación de algunos componentes del cuádriceps (recto femoral, vasto lateral y vasto intermedio) fueron medidas mediante ultrasonografía en modo-B.

Resultados: Hubo diferencias significativas al evaluar los 3 grupos de niños en las variables que miden la calidad del músculo: eco-intensidad y porcentaje de grasa del recto femoral (p < 0.05), espesor muscular del anterior (p < 0.05) y del lateral (p < 0.01) vasto intermedio, y en el ángulo de penneación del recto femoral (ARF) (p < 0.05) y del vasto lateral (AVL) (p < 0.01). Entre los grupos b y c se encontraron diferencias en el ARF en niños (p < 0.01) y en el AVL en niñas (p < 0.05).

Conclusión: La forma en la que se realiza la iniciación deportiva en niños entre 7 y 10 años puede causar diferencias en el cuádriceps, que pueden hacerse evidentes mediante el uso de la ecografía cuantitativa. Estos cambios están además relacionados con la duración y la frecuencia del estímulo, lo cual supone un aspecto cualitativo que debe tomarse en cuenta en la programación de los contenidos de entrenamiento en estas edades.
Introduction

Skeletal muscle in growing children has not been thoroughly studied due to the requirement of invasive methods, such as biopsies, which, for ethical reasons, cannot be applied in minors. However, advancements in imaging techniques have progressively changed the situation and, nowadays, studies are being conducted with children and adolescents, even longitudinal studies, to analyze the muscle tissue at the metabolic and biochemical levels with magnetic resonance imaging (MRI), computerized tomography (CT) and ultrasonography (US). US and dual energy x-ray absorptiometry (DEXA) can provide beneficial reference information for the follow-up of adaptations to training, nutritional regimes and injuries. Some studies have demonstrated that the effects of strength training on the physiological cross-sectional area of the muscle and on strength in children have a similar direction and a different magnitude with respect to adults. It has also been reported that muscle strength, muscle thickness and eco-intensity (EI) (the latter two measured by US) are affected by changes in body weight, height and age in minors. This influence only shows relevant changes in muscle strength and muscle thickness, since little is known about changes in muscle quality measured by EI. The few studies that have analysed these effects show significant changes in healthy children. EI in adults increases along the years, whereas in children it is not associated with age. That is, throughout childhood, during the normal development of the muscles, EI does not change significantly. In any case, there is little information about the effects of physical activity and sport training on muscle quality measured by US through EI.

Studies based on the evaluation of skeletal muscle in growing children, different measurements have been employed, such as muscle strength, muscle power, anthropometry, magnetic resonance imaging (MRI), computerized tomography (CT) and ultrasonography (US). US and dual energy x-ray absorptiometry (DEXA) can provide beneficial reference information for the follow-up of adaptations to training, nutritional regimes and injuries. Some studies have demonstrated that the effects of strength training on the physiological cross-sectional area of the muscle and on strength in children have a similar direction and a different magnitude with respect to adults. It has also been reported that muscle strength, muscle thickness and eco-intensity (EI) (the latter two measured by US) are affected by changes in body weight, height and age in minors. This influence only shows relevant changes in muscle strength and muscle thickness, since little is known about changes in muscle quality measured by EI. The few studies that have analysed these effects show significant changes in healthy children. EI in adults increases along the years, whereas in children it is not associated with age. That is, throughout childhood, during the normal development of the muscles, EI does not change significantly. In any case, there is little information about the effects of physical activity and sport training on muscle quality measured by US through EI.

To evaluate the evolution of skeletal muscle in growing children, different measurements have been employed, such as muscle strength, muscle power, anthropometry, magnetic resonance imaging (MRI), computerized tomography (CT) and ultrasonography (US). US and dual energy x-ray absorptiometry (DEXA) can provide beneficial reference information for the follow-up of adaptations to training, nutritional regimes and injuries. Some studies have demonstrated that the effects of strength training on the physiological cross-sectional area of the muscle and on strength in children have a similar direction and a different magnitude with respect to adults. It has also been reported that muscle strength, muscle thickness and eco-intensity (EI) (the latter two measured by US) are affected by changes in body weight, height and age in minors. This influence only shows relevant changes in muscle strength and muscle thickness, since little is known about changes in muscle quality measured by EI. The few studies that have analysed these effects show significant changes in healthy children. EI in adults increases along the years, whereas in children it is not associated with age. That is, throughout childhood, during the normal development of the muscles, EI does not change significantly. In any case, there is little information about the effects of physical activity and sport training on muscle quality measured by US through EI.

Participants

The study was conducted in an intentional sample of 184 schoolchildren, 75 girls (9.41±0.91 years old) and 109 boys (8.97±1.14 years old), from two sports initiation schools and a primary education school of Medellin, Colombia. The exclusion criteria considered were: the presence of cardiovascular or metabolic disease, muscle-bone lesions or sexual maturation self-reported Tanner stage different from 1. The children and their parents signed an informed assent and consent, respectively. The study protocol was approved by the ethics committee of the Jaime Isaza Cadavid Colombian Polytechnic University. The characteristics of the participants are shown in Table 1.

Design

A transversal, comparative, non-randomised study was carried out. All participants attended either the laboratory of the Jaime Isaza Cadavid Colombian Polytechnic University or a room adapted to serve as a laboratory in the facilities of the San José de las Vegas School and the Lucrecio Jaramillo School (all three institutions located in Medellin, Colombia), between October 2018 and March 2019, where the following anthropometric measurements were recorded: body weight, height and fat percentage. Then, ultrasound imaging was conducted on the right quadriceps of the participants. The study variables are described below.

Quantitative ultrasound

Transversal and longitudinal images were obtained for the quadriceps femoris of the right leg using a B-mode ultrasound imaging device (B-Ultrasound Diagnostic System, Contec, CM5600P2, Republic of China). A linear transducer (gain: 58, frequency: 7.5 MHz; depth: 6 cm), covered with enough water-soluble transmitter gel to avoid the compression of the dermal surface, was placed on two anatomical points: 1) in the anterior region, at the middle point between the antero-superior iliac spine, and 2) in the lateral region, at the middle point between the antero-superior iliac spine and the superior-external angle of the patella. In each anatomical point, longitudinal and transversal ultrasound sections were performed to evaluate the femoral rectus and vast intermediate (anterior region)\(^4\) and the vast lateral and vast intermediate (lateral region)\(^5\). The subjects were evaluated in supine position, at a minimum rest of 5 min, and they were asked to do no vigorous physical effort that day before the measurement. Two longitudinal and two transversal images were taken for each middle point. The frozen image was digitalised and later analysed using the ImageJ free software (National Institute of Health, USA, v.IJ 1.46). The anterior transversal images were used to measure the muscle thickness of the rectus femoris (lower margin of the anterior fascia of the rectus femoris to the upper margin of the posterior fascia of the rectus femoris), the thickness of the vastus intermedius (lower margin of the intermuscular fascia and the periosteum of the femur), and the total thickness of the anterior quadriceps (lower margin of the rectus femoris to the periosteum of the femur) (Figure 1)\(^4\). The lateral transversal images were used to measure: the muscle thickness of the vastus externus (lower margin of the anterior fascia of the vastus externus to the upper margin of the posterior fascia of the vastus externus), the thickness of the vastus intermedius in lateral view (lower margin of the intermuscular fascia and the periosteum of the femur), and the total thickness of the lateral quadriceps (lower margin of the vastus externus to the periosteum of the femur) (Figure 2)\(^5\). The transversal images were also used to determine the EI of the different muscles evaluated using the histogram tool in ImageJ. The region of interest was selected as the largest rectangular area of each muscle excluding fascia. The mean of the two images was expressed as a value between 0 (black) and 1 (white).

Figure 1. Images of the anterior region of the thigh.
225 (white). The EI was correlated to the subcutaneous cell tissue, as suggested by Young, and the fat percentage was measured using the method proposed by the same author for every muscle. Moreover, as a control strategy, the difference in fat EI with respect to each portion of the quadriceps evaluated was also determined (Dif1 to Dif6). The longitudinal images were used to determine the pennation angle of the rectus femoris and the vastus externus. The values used for the statistical analysis of the muscle thickness and the penetration angle were the mean of the two measurements of each image. The coefficient of variation of two measurements, at different moments of the same day for ten subjects, was 5%, 0.4% and 0.8% for muscle thickness, EI and pennation angle, respectively.

**Anthropometry**

Body mass and height were measured without footwear and in sports clothes. Body fat percentage was estimated following Lohman’s method for skinfolds measured in two places: triceps and subscapula.

**Sports**

Sports practice was divided into three groups. The vertical sport initiation group (soccer), was composed of children who only practised soccer. This group trained 3 times per week (Tuesday, Thursday and Saturday), for 120 minutes per session. The structure of the training session approaches physical, technical and tactical contents from an integral perspective, applying such contents to specific game situation. The training sessions were divided into 8 blocks, which included stretching, core proprioception and stability, strength, speed, aerobic resistance, general technique, specific technique, sectorial soccer and integrated competitive soccer. The horizontal sport initiation group (multisport) was constituted by children who practised volleyball, basketball, swimming, gymnastics and cheerleading. The training of the multisport group included mostly contents related to physical coordination attributes and, secondarily, physical condition attributes. Obviously, by working on the different motor capacities and abilities, the children also developed their physical condition. This group applied a global and playful methodology, with no special influence on the development of any attribute. The multisport children trained once per week, for 3 hours, rotating through different sports. Only the girls who practiced cheerleading trained twice per week, for 1.5 hours per session. The third group (no sport) did not practise any sport in a sport club on a regular basis.

**Statistical analysis**

The descriptive analysis of the sociodemographic and ultrasound aspects was carried out using absolute frequencies, relative frequencies and summary indicators such as arithmetic mean, standard deviation,
Study on the differences in quantitative ultrasound of the quadriceps between schoolchildren who practise different sports

Discussion

Eco-intensity

In this study, statistically significant differences were found between the children who practised soccer and the other two groups of participants in the EI of the rectus femoris and vastus intermedius (EIRF, FPRF, Dif1, Dif3). These differences appear in the measurements that include the rectus femoris. Previous studies without the type of sport initiation as a differentiating variable have shown that EI in children does not change during normal growth\(^{19}\). A study conducted by Jacobs et al. (2013), with 25 children aged between 0 and 12 years, concluded that eco-intensity was not influenced by weight, height or age in healthy children, since the changes observed were not significant\(^6\). Another study reported that no changes were observed in age in the grayscale level, since there were no abnormal deposits of fat or connective tissue\(^20\). As the muscle grows, the ultrasound images will start showing the different muscle membranes, which can increase the EI\(^6\), although muscle fiber thickness increases, which decreases the contribution of fibrous tissue, thus increasing the muscle tissue and, consequently, decreasing the EI. In the

Results

The sample was divided into 3 groups according to the sport practised and also by gender. Due to the fact that only one girl practised soccer, she was excluded from the statistical analysis. Consequently, the statistical analysis of the girls only included two groups: multisport and no sport. Table 2 shows the results of the boys in the three groups, and Table 3 presents the results of the two groups for boys and girls.

present study, the decrease of EI could be due to a muscle fiber increase, caused by the different type of sport initiation (practice regularity, training content orientation, etc.). According to the results obtained in this study, quantitative ultrasonography could accurately measure the changes in muscle size, especially muscle thickness, with an excellent correlation with the physiological cross-section area\(^21,22\). EI is modified by training in adult people\(^23\), and fat replacement is the main cause of muscle EI increase in them\(^8\). The results of a different study indicate that, for adolescent children, leg muscle quality is not significantly influenced by maturation\(^24\). A study conducted with men aged between 19 and 68 years compared muscle fat, measured by US, with health and physical activity indicators, and concluded that intramuscular fat was inversely associated with physical activity\(^25\). In our study, the differences found in the analysed groups show that there is a relationship between physical stimuli and changes in muscle quality. The main difference was the decrease of EI, which has not been explained yet in children. A possible explanation would be the decrease of intramuscular fat, measured by ultrasonography, with an increase of muscle fiber size. According to these results, ultrasonography could be considered as a tool to measure the effects of exercise performed by children, in terms of proper stimuli to generate measurable muscle changes. The statistical difference in these components of the quadriceps may be due to the specialisation of the training carried out by the soccer group, who performed a larger number of specific kicking exercises, with a greater orientation to physical work for the muscle groups evaluated and, particularly, the rectus femoris. However, this did not happen in the multisport group, whose practice frequency was lower, as well as the orientation of their exercises, which were rather focused on coordination work and motor competence, with conditional capacities such as strength being less important. This fact suggests that there are no significant differences between the multisport group and the no sport group in both genders. It is worth highlighting the subtraction of fat EI minus muscle EI, measured in our study with variables Dif1 and Dif3, which showed statistically significant differences. As an internal reference of the subject, subcutaneous fat tissue EI allows its comparison with other ultrasound results, offering a way to better evaluate the changes generated by physical activity in

schoolchildren. This could be a useful tool to determine whether the type of physical exercise performed by the child is enough to generate changes in muscle tissue, which is the main tissue involved in both movement and metabolic aspects.

Fat and muscle thickness

Mean fat thickness in the anterior and lateral regions was different and statistically significant between the three groups of children. The lowest values were obtained in the soccer group, whereas the highest values were shown by the no sport group, who did not perform any physical practice on a regular basis. These results corresponded to the fat percentage measured by skinfold (Table 1). Between the multisport and no sport groups, the differences were not significant, neither in boys nor girls. These results suggest that the specific components of sport and, specifically, the orientation of the training contents, could be intense, long and frequent enough to maintain the fat values under the values of children who do not exercise regularly. This could help to establish reference indicators, which, in addition, would be consistent with some of the recommendations found in the literature about the characteristics of exercise in minors.

The thickness of the vastus intermedius measured in the anterior and external regions (VIT, VITE) was significantly different between the three groups, with the lowest values in the soccer group. There were no differences in muscle thickness between the multisport and no sport groups in boys, whereas in girls there was a significant difference only in RFT. Muscle thickness and, particularly, the diameter of human muscle fibre, increase with age and is related to greater muscle strength with respect to the no sport group. These results are in line with the results of our study, since the mean age of the groups is lower in the soccer group and higher in the no sport group, in both boys and girls (boys: "soccer": 8.9±1.16; " multisport": 9.2±1.04; "no sport": 9.8±0.55. Girls: "multisport": 9.1±1.07; "no sport": 9.8±0.55).

Pennation angle

The difference in pennation angle was statistically significant in boys for the two muscles evaluated, i.e., rectus femoris and vastus lateralis, between the three groups. Between the multisport and no sport groups, there were significant differences in ARF in boys and in AVL in girls. All these differences caused an increase in the pennation angle in the soccer group with respect to the other two groups, and in the multisport group with respect to the no sport group. These results are in line with the idea that a greater pennation angle is related to greater muscle strength in children aged between 7 and 10 years, may generate differences in the quadriceps, which can be shown by quantitative muscle ultrasonography. Such changes would be related to the duration and frequency of stimuli, which can be a useful tool for trainers in the planning of the training contents. This can induce a qualitative improvement of the effect of the exercises, determined by their specific orientation.

Limitations

Due to the inherent difficulties of research in our area, mainly caused by the scarcity of financial resources and the social conditions of the city, it was not possible to recruit a larger sample, to include, for instance, a greater number of girls in the soccer group. Furthermore, the results are determined by the difference in the number of practice days per week. Future studies should compare groups with different types of sport initiation and the same frequency of weekly practice.

Conflict of interest

The authors do not declare a conflict of interest.
