A Unified Successive Pseudo-Convex Approximation Framework

Yang Yang and Marius Pesavento

Abstract—In this paper, we propose a successive pseudo-convex approximation algorithm to efficiently compute stationary points for a large class of possibly nonconvex optimization problems. The stationary points are obtained by solving a sequence of successively refined approximate problems, each of which is much easier to solve than the original problem. To achieve convergence, the approximate problem only needs to exhibit a weak form of convexity, namely, pseudo-convexity. We show that the proposed framework not only includes as special cases a number of existing methods, for example, the gradient method and the Jacobi algorithm, but also leads to new algorithms which enjoy easier implementation and faster convergence speed. We also propose a novel line search method for nondifferentiable optimization problems, which is carried out over a properly constructed differentiable function with the benefit of a simplified implementation as compared to state-of-the-art line search techniques that directly operate on the original nondifferentiable objective function. The advantages of the proposed algorithm are shown, both theoretically and numerically, by several example applications, namely, MIMO broadcast channel capacity computation, energy efficiency maximization in massive MIMO systems and LASSO in sparse signal recovery.

Index Terms—Energy efficiency, exact line search, LASSO, massive MIMO, MIMO broadcast channel, nonconvex optimization, nondifferentiable optimization, successive convex approximation.

I. INTRODUCTION

In this paper, we propose an iterative algorithm to solve the following general optimization problem:

\[
\begin{align*}
\text{minimize} & \quad f(x) \\
\text{subject to} & \quad x \in X,
\end{align*}
\]

where \(X \subseteq \mathbb{R}^n\) is a closed and convex set, and \(f : \mathbb{R}^n \to \mathcal{R}\) is a proper and differentiable function with a continuous gradient. We assume that problem (1) has a solution.

Problem (1) also includes some class of nondifferentiable optimization problems, if the nondifferentiable function \(g(x)\) is convex:

\[
\begin{align*}
\text{minimize} & \quad f(x) + g(x) \\
\text{subject to} & \quad x \in X,
\end{align*}
\]

because problem (2) can be rewritten into a problem with the form of (1) by the help of auxiliary variables:

\[
\begin{align*}
\text{minimize} & \quad f(x) + y \\
\text{subject to} & \quad x \in X, \quad g(x) \leq y.
\end{align*}
\]

We do not assume that \(f(x)\) is convex, so (1) is in general a nonconvex optimization problem. The focus of this paper is on the development of efficient iterative algorithms for computing the stationary points of problem (1). The optimization problem (1) represents general class of optimization problems with a vast number of diverse applications. Consider for example the sum-rate maximization in the MIMO multiple access channel (MAC) \([1]\), the broadcast channel (BC) \([2]\) and the interference channel (IC) \([3, 4]\), where \(f(x)\) is the sum-rate function of multiple users (to be maximized) while the set \(X\) characterizes the users’ power constraints. In the context of the MIMO IC, (1) is a nonconvex problem and NP-hard \([5]\). As another example, consider portfolio optimization in which \(f(x)\) represents the expected return of the portfolio (to be maximized) and the set \(X\) characterizes the trading constraints \([6]\). Furthermore, in sparse (\(l_1\)-regularized) linear regression, \(f(x)\) denotes the least square function and \(g(x)\) is the sparsity regularization function \([7, 8]\).

Commonly used iterative algorithms belong to the class of descent direction methods such as the conditional gradient method and the gradient projection method for the differentiable problem \([9, 10]\) and the proximal gradient method for the nondifferentiable problem \([11, 12]\), which often suffer from slow convergence. To speed up the convergence, the block coordinate descent (BCD) method that uses the notion of the nonlinear best-response has been widely studied \([13, 14, 15]\). In particular, this method is applicable if the constraint set of (1) has a Cartesian product structure \(X = X_1 \times \ldots X_K\) such that

\[
\begin{align*}
\text{minimize} & \quad f(x_1, \ldots, x_K) \\
\text{subject to} & \quad x_k \in X_k, \quad k = 1, \ldots, K.
\end{align*}
\]

The BCD method is an iterative algorithm: in each iteration, only one variable is updated by its best-response \(x_k^{t+1} = \arg \min_{x_k \in X_k} f(x_1^{t+1}, \ldots, x_{k-1}^{t+1}, x_k, x_{k+1}^{t+1}, \ldots, x_K^{t+1})\) (i.e., the point that minimizes \(f(x)\) with respect to \(x\) while the remaining variables are fixed to their values of the preceding iteration) and the variables are updated sequentially. This method and its variants have been successfully adopted to many practical problems \([1, 6, 7, 10, 16]\).

When the number of variables is large, the convergence speed of the BCD method may be slow due to the sequential...
nature of the update. A parallel variable update based on the best-response seems attractive as a mean to speed up the updating procedure, however, the convergence of a parallel best-response algorithm is only guaranteed under rather restrictive conditions, c.f. the diagonal dominance condition on the objective function $f(x_1, \ldots, x_K)$ \cite{17}, which is not only difficult to satisfy but also hard to verify. If $f(x_1, \ldots, x_K)$ is convex, the parallel algorithms converge if the stepsize is inversely proportional to the number of block variables $K$. This choice of stepsize, however, tends to be overly conservative in systems with a large number of block variables and inevitably slows down the convergence \cite{2, 10, 18}.

A recent progress in parallel algorithms has been made in \cite{8, 9, 19, 20}, in which it was shown that the stationary point of \cite{1} can be found by solving a sequence of successively refined \textit{approximate problems} of the original problem (1), and convergence to a stationary point is established if, among other conditions, the approximate function (the objective function of the approximate problem) and stepizes are properly selected. The parallel algorithms proposed in \cite{8, 9, 19, 20} are essentially descent direction methods. A description on how to construct the approximate problem such that the convexity of the original problem is preserved as much as possible is also contained in \cite{8, 9, 19, 20} to achieve faster convergence than standard descent directions methods such as classical conditional gradient method and gradient projection method.

Despite its novelty, the parallel algorithms proposed in \cite{8, 9, 19, 20} suffer from two limitations. Firstly, the approximate function must be strongly convex, and this is usually guaranteed by artificially adding a quadratic regularization term to the original objective function $f(x)$, which however may destroy the desirable characteristic structure of the original problem that could otherwise be exploited, e.g., to obtain computationally efficient closed-form solutions of the approximate problems \cite{6}. Secondly, the algorithms require the use of a decreasing stepsize. On the one hand, a slow decay of the stepsize is preferable to make notable progress and to achieve satisfactory convergence speed; on the other hand, theoretical convergence is guaranteed only when the stepsize decays fast enough. In practice, it is a difficult task on its own to find a decay rate for the stepsize that provides a good trade-off between convergence speed and convergence guarantee, and current practices mainly rely on heuristics \cite{19}.

The contribution of this paper consists in the development of a novel iterative convex approximation method to solve problem \cite{1}. In particular, the advantages of the proposed iterative algorithm are the following:

1) The approximate function of the original problem \cite{1} in each iteration only needs to exhibit a weak form of convexity, namely, pseudo-convexity. The proposed iterative method not only includes as special cases many existing methods, for example, \cite{4, 8, 9, 19}, but also opens new possibilities for constructing approximate problems that are easier to solve. For example, in the MIMO BC sum-rate maximization problems (Sec. IV-A), the new approximate problems can be solved in closed-form. We also show by a counterexample that the assumption on pseudo-convexity is tight in the sense that if it is not satisfied, the algorithm may not converge.

2) The stepizes can be determined based on the problem structure, typically resulting in faster convergence than in cases where constant stepizes \cite{2, 10, 18} and decreasing stepizes \cite{8, 19} are used. For example, a constant stepsize can be used when $f(x)$ is given as the difference of two convex functions as in DC programming \cite{21}. When the objective function is nondifferentiable, we propose a new exact/successive line search method that is carried out over a properly constructed differentiable function. Thus it is much easier to implement than state-of-the-art techniques that operate on the original nondifferentiable objective function directly.

In the proposed algorithm, the exact/successive line search is used to determine the stepsize and it can be implemented in a centralized controller, whose existence presence is justified for particular applications, e.g., the base station in the MIMO BC, and the portfolio manager in multi-portfolio optimization \cite{10}. We remark that also in applications in which centralized controller are not admitted, however, the line search procedure does not necessarily imply an increased signaling burden when it is implemented in a distributed manner among different distributed processors. For example, in the LASSO problem studied in Sec. V-C, the stepsize based on the exact line search can be computed in closed-form and it does not incur any additional signaling as in predetermined stepizes, e.g., decreasing stepizes and constant stepizes. Besides, even in cases where the line search procedure induces additional signaling, the burden is often fully amortized by the significant increase in the convergence rate.

The rest of the paper is organized as follows. In Sec. II we introduce the mathematical background. The novel iterative method is proposed and its convergence is analyzed in Sec. III, its connection to several existing descent direction algorithms is presented there. In Sec. IV several applications are considered: the sum rate maximization problem of MIMO BC, the energy efficiency maximization of a massive MIMO system to illustrate the advantage of the proposed approximate function, and the LASSO problem to illustrate the advantage of the proposed stepsize. The paper is finally concluded in Sec. V.

\textbf{Notation:} We use $x$, $X$ and $X$ to denote a scalar, vector and matrix, respectively. We use $X_{jk}$ to denote the $(j,k)$-th element of $X$; $x_k$ is the $k$-th element of $x$ where $x = (x_k)_{k=1}^K$, and $x_{-k}$ denotes all elements of $x$ except $x_k$; $x_{-k} = (x_j)_{j=1, j\neq k}^K$. We denote $x^{-1}$ as the element-wise inverse of $x$, i.e., $(x^{-1})_k = 1/x_k$. Notation $x \circ y$ and $X \otimes Y$ denotes the Hadamard product between $x$ and $y$, and the Kronecker product between $X$ and $Y$, respectively. The operator $\lfloor x \rfloor_a$ returns the element-wise projection of $x$ onto $[a, b]$: $\lfloor x \rfloor_a = \text{max} (\min (x, b), a)$, and $\lceil x \rceil_0 \triangleq \lfloor x \rfloor_0$. We denote $\lfloor x \rfloor$ as the smallest integer that is larger than or equal to $x$. We denote $\text{d}(X)$ as the vector that consists of the diagonal elements of $X$ and $\text{diag}(x)$ is a diagonal matrix whose diagonal elements are same as $x$. We use $\text{I}$ to denote the vector whose elements are equal to 1.

II. PRELIMINARIES ON DESCENT DIRECTION METHOD
AND CONVEX FUNCTIONS

In this section, we introduce the basic definitions and concepts that are fundamental in the development of the mathematical formalism used in the rest of the paper.

Stationary point. A point \( y \in \mathcal{X} \) is a stationary point of \( f(x) \) if
\[
(x - y)^T \nabla f(y) \geq 0, \ \forall x \in \mathcal{X}.
\]

Condition (5) is the necessary condition for local optimality of the variable \( y \). For nonconvex problems, where global optimality conditions are difficult to establish, the computation of stationary points of the optimization problem (1) is generally desired. If (1) is convex, stationary points coincide with (globally) optimal points and condition (5) is also sufficient for \( y \) to be (globally) optimal.

Descent direction. The vector \( d^t \) is a descent direction of the function \( f(x) \) at \( x = x^t \) if
\[
\nabla f(x^t)^T d^t < 0.
\]

If (6) is satisfied, the function \( f(x) \) can be decreased when \( x \) is updated from \( x^t \) along direction \( d^t \). This is because in the Taylor expansion of \( f(x) \) around \( x = x^t \) is given by:
\[
f(x^t + \gamma d^t) = f(x^t) + \gamma \nabla f(x^t)^T d^t + o(\gamma),
\]
where the first order term is negative in view of (6). For sufficiently small \( \gamma \), the first order term dominates all higher order terms. More rigorously, if \( d^t \) is a descent direction, there exists a \( \gamma^t > 0 \) such that [22, 8.2.1]
\[
f(x^t + \gamma d^t) < f(x^t), \forall \gamma \in (0, \gamma^t).
\]
Note that the converse is not necessarily true, i.e., \( f(x^{t+1}) < f(x^t) \) for arbitrary functions \( f(x) \) does not necessarily imply that \( x^{t+1} - x^t \) is a descent direction of \( f(x) \) at \( x = x^t \).

Quasi-convex function. A function \( h(x) \) is quasi-convex if for any \( \alpha \in [0, 1] \):
\[
h((1 - \alpha)x + \alpha y) \leq \max(h(x), h(y)), \ \forall x, y \in \mathcal{X}.
\]
A locally optimal point \( y \) of a quasi-convex function \( h(x) \) over a convex set \( \mathcal{X} \) is also globally optimal, i.e.,
\[
h(x) \geq h(y), \ \forall x \in \mathcal{X}.
\]

Pseudo-convex function. A function \( h(x) \) is pseudo-convex if [23]
\[
\nabla h(x)^T(y - x) \geq 0 \implies h(y) \geq h(x), \ \forall x, y \in \mathcal{X}.
\]
Another equivalent definition of pseudo-convex functions is also useful in our context [23]:
\[
h(y) < h(x) \implies \nabla h(x)^T(y - x) < 0.
\]
In other words, \( h(y) < h(x) \) implies that \( y - x \) is a descent direction of \( h(x) \). A pseudo-convex function is also quasi-convex [23, Th. 9.3.5], and thus any locally optimal points of pseudo-convex functions are also globally optimal.

Convex function. A function \( h(x) \) is convex if
\[
h(y) \geq h(x) + \nabla h(x)^T(y - x), \ \forall x, y \in \mathcal{X}.
\]

It is strictly convex if the above inequality is satisfied with strict inequality whenever \( x \neq y \). It is easy to see that a convex function is pseudo-convex.

Strongly convex functions. A function \( h(x) \) is strongly convex with constant \( a \) if
\[
h(y) \geq h(x) + \nabla h(x)^T(y - x) + \frac{a}{2} \|y - x\|^2, \ \forall x, y \in \mathcal{X},
\]
for some positive constant \( a \). The relationship of functions with different degree of convexity is summarized in Figure 1 where the arrow denotes implication in the direction of the arrow.

III. THE PROPOSED SUCCESSIVE PSEUDO-CONVEX APPROXIMATION ALGORITHM

In this section, we propose an iterative algorithm that solves (1) as a sequence of successively refined approximate problems, each of which is much easier to solve than the original problem (1), e.g., the approximate problem can be decomposed into independent subproblems that might even exhibit closed-form solutions.

In iteration \( t \), let \( \tilde{f}(x; x^t) \) be the approximate function of \( f(x) \) around the point \( x^t \). Then the approximate problem is
\[
\begin{align*}
\text{minimize} & \quad \tilde{f}(x; x^t) \\
\text{subject to} & \quad x \in \mathcal{X},
\end{align*}
\]
and its optimal point and solution set is denoted as \( \mathbb{B}x^t \) and \( S(x^t) \), respectively:
\[
\mathbb{B}x^t \subseteq S(x^t) \triangleq \left\{ x^t \in \mathcal{X} : \tilde{f}(x^t; x^t) = \min_{x \in \mathcal{X}} \tilde{f}(x; x^t) \right\}.
\]
We assume that the approximate function \( \tilde{f}(x; y) \) satisfies the following technical conditions:

(A1) The approximate function \( \tilde{f}(x; y) \) is pseudo-convex in \( x \) for any given \( y \in \mathcal{X} \);

(A2) The approximate function \( \tilde{f}(x; y) \) is continuously differentiable in \( x \) for any given \( y \in \mathcal{X} \) and continuous in \( y \) for any \( x \in \mathcal{X} \);

(A3) The gradient of \( \tilde{f}(x; y) \) and the gradient of \( f(x) \) are identical at \( x = y \) for any \( y \in \mathcal{X} \), i.e., \( \nabla_x \tilde{f}(y; y) = \nabla_x f(y) \);

Based on (9), we define the mapping \( \mathbb{B}x \) that is used to generate the sequence of points in the proposed algorithm:
\[
\mathcal{X} \ni x \mapsto \mathbb{B}x \in \mathcal{X}.
\]

Given the mapping \( \mathbb{B}x \), the following properties hold.
Proposition 1 (Stationary point and descent direction). Provided that Assumptions (A1)-(A3) are satisfied: (i) A point \( y \) is a stationary point of \( f \) if and only if \( y \in \mathcal{S}(y) \) defined in (9); (ii) If \( y \) is not a stationary point of \( f \), then \( B_y - y \) is a descent direction of \( f(x) \):

\[
\nabla f(y)^T (B_y - y) < 0. \tag{11}
\]

Proof: See Appendix A.

If \( x^t \) is not a stationary point, according to Proposition 1, we define the vector update \( x^{t+1} \) in the \((t+1)\)-th iteration as:

\[
x^{t+1} = x^t + \gamma^t (Bx^t - x^t), \tag{12}
\]

where \( \gamma^t \in (0, 1] \) is an appropriate stepsize that can be determined by either the exact line search (also known as the minimization rule) or the successive line search (also known as the Armijo rule). Since \( x^t \in X, Bx^t \in X \) and \( \gamma^t \in (0, 1] \), it follows from the convexity of \( X \) that \( x^{t+1} \in X \) for all \( t \).

Exact line search. The stepsize is chosen such that the function \( f(x) \) is decreased to the largest extent along the descent direction \( Bx^t - x^t \):

\[
\gamma^t \in \arg \min_{0 \leq \gamma \leq 1} f(x^t + \gamma(Bx^t - x^t)). \tag{13}
\]

With this stepsize rule, it is easy to see that if \( x^t \) is not a stationary point, then

\[
f(x^{t+1}) < f(x^t).
\]

In the special case that \( f(x) \) in (1) is convex and \( \gamma^* \) nulls the gradient of \( f(x^t + \gamma_1(Bx^t - x^t)) \), then \( \gamma^* \) in (15) is simply the projection of \( \gamma^* \) onto the interval \([0, 1] \):

\[
\gamma^t = [\gamma^*]^1_{0} = \begin{cases} 1, & \text{if } \nabla f(x^t + \gamma(Bx^t - x^t))|_{\gamma=1} \geq 0, \\ 0, & \text{if } \nabla f(x^t + \gamma(Bx^t - x^t))|_{\gamma=0} \leq 0, \\ \gamma^*, & \text{otherwise}. \end{cases}
\]

If \( 0 \leq \gamma^t = \gamma^* \leq 1 \), the constrained optimization problem in (15) is essentially unconstrained. In some applications it is possible to compute \( \gamma^* \) analytically, e.g., if \( f(x) \) is quadratic in the LASSO problem (Sec. IV-C). Otherwise, for general convex functions, \( \gamma^* \) can be found efficiently by the bisection method as follows. Restricting the function \( f(x) \) to a line \( x^t + \gamma(Bx^t - x^t) \), the new function \( f(x^t + \gamma(Bx^t - x^t)) \) is convex in \( \gamma \). Thus follows that \( \nabla f(x^t + \gamma(Bx^t - x^t)) \geq 0 \) if \( \gamma < \gamma^* \) and \( \nabla f(x^t + \gamma(Bx^t - x^t)) \geq 0 \) if \( \gamma > \gamma^* \). Given an interval \([\gamma_{low}, \gamma_{up}] \) containing \( \gamma^* \) (the initial value of \( \gamma_{low} \) and \( \gamma_{up} \) is 0 and 1, respectively), set \( \gamma_{mid} = (\gamma_{low} + \gamma_{up})/2 \) and refine \( \gamma_{low} \) and \( \gamma_{up} \) according to the following rule:

\[
\begin{align*}
\gamma_{low} &= \gamma_{mid}, & \text{if } \nabla f(x^t + \gamma_{mid}(Bx^t - x^t)) > 0, \\
\gamma_{up} &= \gamma_{mid}, & \text{if } \nabla f(x^t + \gamma_{mid}(Bx^t - x^t)) < 0.
\end{align*}
\]

The procedure is repeated for finite times until the gap \( \gamma_{up} - \gamma_{low} \) is smaller than a prescribed precision.

Successive line search. If no structure in \( f(x) \) (e.g., convexity) can be exploited to efficiently compute \( \gamma^t \) according to the exact line search (15), the successive line search can instead be employed: given scalars \( 0 < \alpha < 1 \) and \( 0 < \beta < 1 \), the stepsize \( \gamma^t \) is set to be \( \gamma^t = \beta^m \), where \( m_t \) is the smallest nonnegative integer \( m \) satisfying the following inequality:

\[
f(x^t + \beta^m(Bx^t - x^t)) \leq f(x^t) + \alpha \beta^m \nabla f(x^t)^T(Bx^t - x^t). \tag{14}
\]

Note that the existence of a finite \( m_t \) satisfying (14) is always guaranteed if \( Bx^t - x^t \) is a descent direction at \( x^t \) and \( \nabla f(x^t)^T(Bx^t - x^t) < 0 \) (13), i.e., from Proposition 1 inequality (14) always admits a solution.

The algorithm is formally summarized in Algorithm 1 and its convergence properties are given in the following theorem.

Theorem 2 (Convergence to a stationary point). Consider the sequence \( \{x^t\} \) generated by Algorithm 1. Provided that Assumptions (A1)-(A3) as well as the following assumptions are satisfied:

(A4) The solution set \( S(x^t) \) is nonempty for \( t = 1, 2, \ldots \);

(A5) Given any convergent subsequence \( \{x^t\} \subseteq X \), the sequence \( \{Bx^t\} \subseteq X \) is bounded.

Then any limit point of \( \{x^t\} \) is a stationary point of \( f \).

Proof: See Appendix B.

In the following we discuss some properties of the proposed Algorithm 1.

On the conditions (A1)-(A5). The only requirement on the convexity of the approximate function \( f(x; x^t) \) is that it is pseudo-convex, cf. (A1). To the best of our knowledge, these are the weakest conditions for descent direction methods available in the literature. As a result, it enables the construction of new approximate functions that can often be optimized more easily or even in closed-form, resulting in a significant reduction of the computational cost. Assumptions (A2)-(A3) represent standard conditions for successive convex approximation techniques and are satisfied for many existing approximation functions, cf. Sec. III-B. Sufficient conditions for Assumptions (A4)-(A5) are that either the feasible set \( X \) in (6) is bounded or the approximate function in (6) is strongly convex (23). We show that these assumptions are satisfied in popular applications considered in Sec. IV-V.

On the pseudo-convexity of the approximate function. Assumption (A1) is tight in the sense that if it is not satisfied, Proposition 1 may not hold. Consider the following simple example: \( f(x) = x^3 \), where \(-1 \leq x \leq 1 \) and the point \( x^t = 0 \) at iteration \( t \). Choosing the approximate function \( f(x; x^t) = x^3 \), which is quasi-convex but not pseudo-convex, all assumptions except (A1) are satisfied. It is easy to see that \( Bx^t = -1 \), however \( (Bx^t - x^t) \nabla f(x^t) = (-1 - 0) \cdot 0 = 0 \),
and thus \( Bx^t - x^t \) is not a descent direction, i.e., inequality (11) in Proposition 1 is violated.

**On the stepsize.** The stepsize can be determined in a more straightforward way if \( f(x; x') \) is a global upper bound of \( f(x) \) that is exact at \( x = x' \), i.e., assume that (A6) \( f(x; x') \geq f(x) \) and \( f(x'; x') = f(x') \), then Algorithm 1 converges under the choice \( \gamma^t = 1 \) which results in the update \( x^{t+1} = Bx^t \). To see this, we first remark that \( \gamma^t = 1 \) must be an optimal point of the following problem:

\[
1 \in \arg\min_{0 \leq \gamma \leq 1} \tilde{f}(x^t + \gamma(Bx^t - x^t); x^t),
\]

otherwise the optimality of \( Bx^t \) is contradicted, cf. (9).

At the same time, it follows from Proposition 1 that
\[
\nabla \tilde{f}(x^t; x^t)^T(Bx^t - x^t) < 0.
\]

The successive line search over \( \tilde{f}(x' + \gamma(Bx^t - x^t)) \) thus yields a nonnegative and finite integer \( m_t \) such that for some \( 0 < \alpha < 1 \) and \( 0 < \beta < 1 \):

\[
\tilde{f}(Bx^t; x^t) \leq \tilde{f}(x^t + \beta^m(Bx^t - x^t); x^t) \\
\leq \tilde{f}(x^t) + \alpha \beta^m \nabla \tilde{f}(x^t; x^t)^T(Bx^t - x^t) \\
= f(x^t) + \alpha \beta^m \nabla f(x^t)^T(Bx^t - x^t),
\]

where the second inequality comes from the definition of successive line search [cf. (14)] and the last equality follows from Assumptions (A3) and (A6). Invoking Assumption (A6) again, we obtain

\[
f(x^{t+1}) \leq f(x^t) + \alpha \beta^m \nabla f(x^t)^T(Bx^t - x^t)
\]

The proof of Theorem 2 can be used verbatim to prove the convergence of Algorithm 1 with a constant stepsize \( \gamma^t = 1 \).

**A. Nondifferentiable Optimization Problems**

In the following we show that the proposed Algorithm 1 can be applied to solve problem (3), and its equivalent formulation (2) which contains a nondifferentiable objective function. Suppose that \( f(x; x') \) is an approximate function of \( f(x) \) in (3) around \( x^t \) and it satisfies Assumptions (A1)-(A3). Then the approximation of problem (3) around \( x^t \) is\footnote{Algorithm 2}

\[
(Bx^t, y^*(x^t)) \triangleq \arg\min_{x \in X, y \in y} \tilde{f}(x; x') + y.
\]

That is, we only need to replace the differentiable function \( f(x) \) by its approximate function \( \tilde{f}(x; x') \). To see this, it is sufficient to verify Assumption (A3) only:

\[
\nabla_x (\tilde{f}(x; x') + y) = \nabla_x (f(x) + y), \\
\nabla_y (\tilde{f}(x; x') + y) = \nabla_y (f(x) + y) = 1.
\]

Based on the exact line search, the stepsize \( \gamma^t \) in this case is given as

\[
\gamma^t \in \arg\min_{0 \leq \gamma \leq 1} \{ f(x^t + \gamma(Bx^t - x^t)) + y^t + \gamma(y^*(x^t) - y^t) \},
\]

where \( y^t \geq g(x^t) \). Then the variables \( x^{t+1} \) and \( y^{t+1} \) are defined as follows:

\[
x^{t+1} = x^t + \gamma^t(Bx^t - x^t),
\]

\[
y^{t+1} = y^t + \gamma^t(y^*(x^t) - y^t).
\]

The convergence of Algorithm 1 with \( (Bx^t, y^*(x^t)) \) and \( \gamma^t \) given by (18)-(19) directly follows from Theorem 2.

The point \( y^{t+1} \) given in (20b) can be further refined:

\[
f(x^{t+1}) + y^{t+1} = f(x^{t+1}) + y^t + \gamma^t(y^*(x^t) - y^t) \\
\geq f(x^{t+1}) + g(x^t) + \gamma^t(g(Bx^t) - g(x^t)) \\
\geq f(x^{t+1}) + g((1 - \gamma^t)x^t + \gamma^tBx^t) \\
= f(x^{t+1}) + g(x^{t+1}),
\]

where the first and the second inequality comes from the fact that \( y^t \geq g(x^t) \) as well as \( y^*(x^t) = g(Bx^t) \) and Jensen’s inequality of convex functions \( g(x) \) respectively. Since \( y^{t+1} \geq g(x^{t+1}) \) by definition, the point \( (x^{t+1}, g(x^{t+1})) \) always yields a lower value of \( f(x) + y \) than \( (x^{t+1}, y^{t+1}) \) while \( (x^{t+1}, g(x^{t+1})) \) is still a feasible point for problem (3). The update (20b) is then replaced by the following enhanced rule:

\[
y^{t+1} = g(x^{t+1}).
\]

Algorithm 1 with \( Bx^t \) given in (20a) and \( y^{t+1} \) given in (21) still converges to a stationary point of (3).

The notation in (18)-(19) can be simplified by removing the auxiliary variable \( y^* \): \( Bx^t \) in (18) can be equivalently written as

\[
Bx^t = \arg\min_{x \in X} \{ f(x; x') + g(x) \}
\]

and combining (19) and (21) yields

\[
\gamma^t \in \arg\min_{0 \leq \gamma \leq 1} \{ f(x^t + \gamma(Bx^t - x^t)) + \gamma g(Bx^t) - g(x^t) \}.
\]

In the context of the successive line search, customizing the general definition (14) for problem (3) yields the choice \( \gamma^t = \beta^m \) with \( m_t \) being the smallest integer that satisfies the inequality:

\[
f(x^t + \beta^m(Bx^t - x^t)) \leq f(x^t) + \beta^m(\alpha \nabla f(x^t)^T(Bx^t - x^t) + (\alpha - 1)(g(Bx^t) - g(x^t))).
\]

Based on the derivations above, the proposed algorithm for the nondifferentiable problem (2) is formally summarized in Algorithm 2.

It is much easier to calculate \( \gamma^t \) according to (23) than in state-of-the-art techniques that directly carry out the exact line search.
search over the original nondifferentiable objective function in \([2, 26, \text{Rule} \ E]\), i.e.,
\[
\min_{0 \leq \gamma \leq 1} \left\{ f(\mathbf{x}^t + \gamma (\mathbb{B}\mathbf{x}^t - \mathbf{x}^t)) + g(\mathbf{x}^t + \gamma (\mathbb{B}\mathbf{x}^t - \mathbf{x}^t)) \right\}.
\]

This is because the objective function in \((23)\) is differentiable in \(\gamma\) while state-of-the-art techniques involve the minimization of a nondifferentiable function. If \(f(\mathbf{x})\) exhibits a specific structure such as in quadratic functions, \(\gamma^t\) can even be calculated in closed-form. This property will be exploited to develop fast and easily implementable algorithm for the popular LASSO problem in Sec. IV-C.

In the proposed successive line search, the left hand side of (24) depends on \(f(\mathbf{x})\) while the right hand side is linear in \(\beta^t\). The proposed variation of the successive line search thus involves only the evaluation of the differentiable function \(f(\mathbf{x})\) and its computational complexity and signaling exchange (when implemented in a distributed manner) is thus lower than state-of-the-art techniques (for example \([26, \text{Rule} \ A^t] , [27] \text{Equations} \-(9)-(10), [19] \text{Remark} \ 4\) and [28] Algorithm 2.1.1), in which the whole nondifferentiable function \(f(\mathbf{x}) + g(\mathbf{x})\) must be repeatedly evaluated (for different \(m_t\)) and compared with a certain benchmark before \(m_t\) is found.

### B. Special Cases and New Algorithms

In this subsection, we interpret some existing methods in the context of Algorithm \([1] \) and show that they can be considered as special cases of the proposed algorithm.

**Conditional gradient method:** In this iterative algorithm for problem \((1)\), the approximate function is given as the first-order approximation of \(f(\mathbf{x})\) at \(\mathbf{x} = \mathbf{x}^t \ [13, \text{Sec.} \ 2.2.2]\), i.e.,
\[
\hat{f}(\mathbf{x}; \mathbf{x}^t) = \nabla f(\mathbf{x}^t)^T (\mathbf{x} - \mathbf{x}^t).
\]

Then the stepsize is selected by either the exact line search or the successive line search.

**Gradient projection method:** In this iterative algorithm for problem \((1)\), the approximate function is given by \([13, \text{Sec.} \ 2.3]\)
\[
\mathbb{B}\mathbf{x}^t = [\mathbf{x}^t - s^t \nabla f(\mathbf{x}^t)]_{\mathcal{X}},
\]
where \(s^t > 0\) and \([\mathbf{x}]_{\mathcal{X}}\) denotes the projection of \(\mathbf{x}\) onto \(\mathcal{X}\). This is equivalent to defining \(f(\mathbf{x}; \mathbf{x}^t)\) in (25) as follows:
\[
\hat{f}(\mathbf{x}; \mathbf{x}^t) = \nabla f(\mathbf{x}^t)^T (\mathbf{x} - \mathbf{x}^t) + \frac{1}{2 s^t} \|\mathbf{x} - \mathbf{x}^t\|_2^2,
\]

which is the first-order approximation of \(f(\mathbf{x})\) augmented by a quadratic regularization term that is introduced to improve the numerical stability \([17]\). A generalization of (26) is to replace the quadratic term by \((\mathbf{x} - \mathbf{x}^t)^H \mathbf{H} (\mathbf{x} - \mathbf{x}^t)\) where \(\mathbf{H} \succ 0 \ [7]\).

**Proximal gradient method:** If \(f(\mathbf{x})\) is convex and has a Lipschitz continuous gradient with a constant \(L\), the proximal gradient method for problem (2) has the following form \([14, \text{Sec.} \ 4.2]\):
\[
\mathbf{x}^{t+1} = \arg \min_{\mathbf{x}} \left\{ s^t g(\mathbf{x}) + \frac{1}{2} \|\mathbf{x} - (\mathbf{x}^t - s^t \nabla f(\mathbf{x}^t))\|_2^2 \right\}
\]
\[
= \arg \min_{\mathbf{x}} \left\{ \nabla f(\mathbf{x}^t)(\mathbf{x} - \mathbf{x}^t) + \frac{1}{2 s^t} \|\mathbf{x} - \mathbf{x}^t\|_2^2 + g(\mathbf{x}) \right\}.
\]

where \(s^t > 0\). In the context of the proposed framework (22), the update (27) is equivalent to defining \(\hat{f}(\mathbf{x}; \mathbf{x}^t)\) as follows:
\[
\hat{f}(\mathbf{x}; \mathbf{x}^t) = \nabla f(\mathbf{x})^T (\mathbf{x} - \mathbf{x}^t) + \frac{1}{2 s^t} \|\mathbf{x} - \mathbf{x}^t\|_2^2
\]

and setting the stepsize \(\gamma^t = 1\) for all \(t\). According to Theorem 2 and the discussion following Assumption (A6), the proposed algorithm converges under a constant unit stepsize if \(f(\mathbf{x}; \mathbf{x}^t)\) is a global upper bound of \(f(\mathbf{x})\), which is indeed the case when \(s^t \leq 1/L\) in view of the descent lemma \([13, \text{Prop.} \ A.24]\).

**Jacobi algorithm:** In problem (1), if \(f(\mathbf{x})\) is convex in each \(x_k\) where \(k = 1, \ldots, K\) (but not necessarily jointly convex in \((x_1, \ldots, x_K)\)), the approximate function is defined as \([3]\)
\[
f(\mathbf{x}; \mathbf{x}^t) = \sum_{k=1}^{K} f(x_k, \mathbf{x}^t_{-k}) + \frac{\tau}{2} \|x_k - x_k^t\|_2^2,
\]

where \(\tau_k \geq 0\) for \(k = 1, \ldots, K\). The \(k\)-th component function \(f(x_k, \mathbf{x}^t_{-k}) + \frac{\tau_k}{2} \|x_k - x_k^t\|_2^2\) in (29) is obtained from the original function \(f(x_k)\) by fixing all variables except \(x_k\), i.e., \(x_{-k} = \mathbf{x}^t_{-k}\), and further adding a quadratic regularization term. Since \(f(\mathbf{x}; \mathbf{x}^t)\) in (29) is convex, Assumption (A1) is satisfied. Based on the observations that
\[
\nabla_{x_k} \hat{f}(\mathbf{x}; \mathbf{x}^t) = \nabla_{x_k} f(x_k, \mathbf{x}^t_{-k}) + \frac{\tau_k}{2} \|x_k - x_k^t\|_2^2 |_{x_k = x_k^t} = \nabla_{x_k} f(x_k, \mathbf{x}^t_{-k}) + \tau_k (x_k - x_k^t) |_{x_k = x_k^t} = \nabla_{x_k} f(x^t_k),
\]

we conclude that Assumption (A3) is satisfied by the choice of the approximate function in (29). The resulting approximate problem is given by
\[
\min_{\mathbf{x} = (x_k)_{k=1}^K} \sum_{k=1}^{K} (f(x_k, \mathbf{x}^t_{-k}) + \frac{\tau_k}{2} \|x_k - x_k^t\|_2^2)
\]

subject to \(\mathbf{x} \in \mathcal{X}\).

This is commonly known as the Jacobi algorithm. The structure inside the constraint set \(\mathcal{X}\), if any, may be exploited to solve (30) even more efficiently. For example, the constraint set \(\mathcal{X}\) consists of separable constraints in the form of \(\sum_{k=1}^{K} h_k(x_k) \leq 0\) for some convex functions \(h_k(x_k).\) Since subproblem (30) is convex, primal and dual decomposition techniques can readily be used to solve (30) efficiently \([29]\) (such an example is studied in Sec. IV-A).

To guarantee the convergence, the condition proposed in (9) is that \(\tau_k > 0\) for all \(k\) in (29) unless \(f(\mathbf{x})\) is strongly convex in each \(x_k\). However, the strong convexity of \(f(\mathbf{x})\) in each \(x_k\) is a strong assumption that cannot always be satisfied and the additional quadratic regularization term that is otherwise required may destroy the convenient structure that could otherwise be exploited, as we will show through an example application in the MIMO BC in Sec. IV-A. In the case \(\tau_k = 0,\) convergence of the Jacobi algorithm (30) is only proved when \(f(\mathbf{x})\) is jointly convex in \((x_1, \ldots, x_K)\) and the stepsize is inversely proportional to the number of variables \(K\) \([2, 10, 13]\), namely, \(\gamma^t = 1/K\). However, the resulting convergence speed is usually slow when \(K\) is large, as we will later demonstrate numerically in Sec. IV-A.

With the technical assumptions specified in Theorem 2 the convergence of the Jacobi algorithm with the approximate problem (30) and successive line search is guaranteed even
Algorithm 3 The Jacobi algorithm for problem (4)

Data: $t = 0$ and $x_k^0 \in X_k$ for all $k = 1, \ldots, K$. Repeat the following steps until convergence:

S1: For $k = 1, \ldots, K$, compute $B_k x^t$ using (31).
S2: Compute $\gamma^t$ by the exact line search (13) or the successive line search (14).
S3: Update $x_k^{t+1}$ according to

$$x_k^{t+1} = x_k^t + \gamma^t (B_k x^t - x_k^t), \forall k = 1, \ldots, K.$$ 

Set $t \leftarrow t + 1.$

when $\tau_k = 0$. This is because $\tilde{f}(x; x')$ in (29) is already convex when $\tau_k = 0$ for all $k$ and it naturally satisfies the pseudo-convexity assumption specified by Assumption (A1).

In the case that the constraint set $\mathcal{X}$ has a Cartesian product structure (4), the subproblem (30) is naturally decomposed into $K$ sub-problems, one for each variable, which are then solved in parallel. In this case, the requirement in the convexity of $f(x)$ in each $x_k$ can even be relaxed to pseudo-convexity only (although the sum function $\sum_{k=1}^K f(x_k, x_{-k})$ is not necessarily pseudo-convex in $x$ as pseudo-convexity is not preserved under nonnegative weighted sum operator), and this leads to the following update: $B_k x^t = (B_k x^t)^t_k$ and

$$B_k x^t \in \arg \min_{x_k \in X_k} f(x_k, x_{-k}^t), \quad k = 1, \ldots, K, \quad (31)$$

where $B_k x^t$ can be interpreted as variable $x_k$’s best-response to other variables $x_{-k} = (x_j)_{j \neq k}$ when $x_{-k} = x_{-k}^t$. The proposed Jacobi algorithm is formally summarized in Algorithm 3 and its convergence is proved in Theorem 3.

Theorem 3. Consider the sequence $\{x^t\}$ generated by Algorithm 3. Provided that $f(x)$ is pseudo-convex in $x_k$ for all $k = 1, \ldots, K$ and Assumptions (A4)-(A5) are satisfied. Then any limit point of the sequence generated by Algorithm 3 is a stationary point of (4).

Proof: See Appendix C.

The convergence condition specified in Theorem 3 relaxes those in [19]: $f(x)$ only needs to be pseudo-convex in each variable $x_k$ and no regularization term is needed (i.e., $\tau_k = 0$).

To the best of our knowledge, this is the weakest convergence condition on Jacobi algorithms available in the literature. We will show in Sec. IV-B by an example application of the energy efficiency maximization problem in massive MIMO systems how the weak assumption on the approximate function’s convexity proposed in Theorem 2 can be exploited to the largest extent. Besides this, the line search usually yields much faster convergence than the fixed stepsize adopted in [12] even under the same approximate problem, cf. Sec. IV-A.

DC algorithm: If the objective function in (4) is the difference of two convex functions $f_1(x)$ and $f_2(x)$:

$$f(x) = f_1(x) - f_2(x),$$

the following approximate function can be used:

$$\tilde{f}(x; x') = f_1(x) - (f_2(x') + \nabla f_2(x')^T (x - x')).$$

Since $f_2(x)$ is convex and $f_2(x) \geq f_2(x') + \nabla f_2(x')^T (x - x')$, Assumption (A6) is satisfied and the constant unit stepsize can be chosen [30].

IV. EXAMPLE APPLICATIONS

A. MIMO Broadcast Channel Capacity Computation

In this subsection, we study the MIMO BC capacity computation problem to illustrate the advantage of the proposed approximate function.

Consider a MIMO BC where the channel matrix characterizing the transmission from the base station to user $k$ is denoted by $H_k$, the transmit covariance matrix of the signal from the base station to user $k$ is denoted as $Q_k$, and the noise at each user $k$ is an additive independent and identically distributed Gaussian vector with unit variance on each of its elements. Then the sum capacity of the MIMO BC is

$$\max_{\{Q_k\}} \log |I + \sum_{k=1}^K H_k Q_k H_k^H|$$

subject to $Q_k \succeq 0$, $k = 1, \ldots, K$, $\sum_{k=1}^K \text{tr}(Q_k) \leq P$, (32)

where $P$ is the power budget at the base station.

Problem (32) is a convex problem whose solution cannot be expressed in closed-form and can only be found iteratively. To apply Algorithm 1 we invoke (29)-(30) and the approximate problem at the $t$-th iteration is

$$\max_{\{Q_k\}} \sum_{k=1}^K \log |R_k (Q^t_k - k) + H_k Q_k H_k^H|$$

subject to $Q_k \succeq 0$, $k = 1, \ldots, K$, $\sum_{k=1}^K \text{tr}(Q_k) \leq P$, (33)

where $R_k (Q^t_k - k) \triangleq I + \sum_{j \neq k} H_j Q^t_j H_j^H$. The approximate function is concave in $Q$ and differentiable in both $Q$ and $Q^t$, and thus Assumptions (A1)-(A3) are satisfied. Since the constraint set in (33) is compact, the approximate problem (33) has a solution and Assumptions (A4)-(A5) are satisfied.

Problem (33) is convex and the sum-power constraint coupling $Q_1, \ldots, Q_K$ is separable, so dual decomposition techniques can be used [29]. In particular, the constraint set has a nonempty interior, so strong duality holds and (33) can be solved from the dual domain by relaxing the sum-power constraint into the Lagrangian (24):

$$\mathbb{E} Q^t = \arg \max_{Q_k \succeq 0} \left\{ \sum_{k=1}^K \log |R_k (Q^t_k - k) + H_k Q_k H_k^H| - \lambda^* \left( \sum_{k=1}^K \text{tr}(Q_k) - P \right) \right\}, \quad (34)$$

where $\mathbb{E} Q^t = \{B_k Q^t\}_{k=1}^K$ and $\lambda^*$ is the optimal Lagrange multiplier that satisfies the following conditions: $\lambda^* > 0$, $\sum_{k=1}^K \text{tr}(B_k Q^t) - P \leq 0$, $\lambda^* \sum_{k=1}^K \text{tr}(B_k Q^t) - P = 0$, and can be found efficiently using the bisection method.

The problem in (33) is uncoupled among different variables $Q_k$ in both the objective function and the constraint set, so it can be decomposed into a set of smaller subproblems which are solved in parallel: $\mathbb{E} Q^t = \{B_k Q^t\}_{k=1}^K$ and

$$\mathbb{E} Q^t = \arg \max_{Q_k \succeq 0} \log |R_k (Q^t_k - k) + H_k Q_k H_k^H| - \lambda^* \text{tr}(Q_k), \quad (35)$$

subject to $Q_k \succeq 0$, $k = 1, \ldots, K$.
and $B_k^t Q^t$ exhibits a closed-form expression based on the waterfilling solution [2]. Thus problem (33) also has a closed-form solution up to a Lagrange multiplier that can be found efficiently using the bisection method. With the update direction $BQ^t - Q^t$, the base station can implement the exact line search to determine the stepsize using the bisection method described after (13) in Sec. [I].

We remark that when the channel matrices $H_k$ are rank deficient, problem (33) is convex but not strongly convex, but the proposed algorithm with the approximate problem (33) still converges. However, if the approximate function in [2] is used [cf. (29)], an additional quadratic regularization term must be included into (33) (and thus (35)) to make the approximate problem strongly convex, but the resulting approximate problem no longer exhibits a closed-form solution and thus are much more difficult to solve.

**Simulations.** The parameters are set as follows. The number of users is $K = 20$ and $K = 100$, the number of transmit and receive antenna is (5,4), and $\bar{P} = 10$ dB. The simulation results are averaged over 20 instances.

We apply Algorithm 1 with approximate problem (33) and stepsize based on the exact line search, and compare it with the iterative algorithm proposed in [2] [18], which uses the same approximate problem (33) but with a fixed stepsize $\gamma^t = 1/K$ ($K$ is the number of users). It is easy to see from Figure 2 that the proposed method converges very fast (in less than 10 iterations) to the sum capacity, while the method of [2] requires many more iterations. This is due to the benefit of the exact line search applied in our algorithm over the fixed stepsize which tends to be overly conservative. Employing the exact line search adds complexity as compared to the simple choice of a fixed stepsize, however, since the objective function of (32) is concave, the exact line search consists in maximizing a differentiable concave function with a scalar variable, and it can be solved efficiently by the bisection method with affordable cost. More specifically, it takes 0.0023 seconds to solve problem (33) and 0.0018 seconds to perform the exact line search (the software/hardware environment is further specified in Sec. [IV-C]). Therefore, the overall CPU time (time per iteration×number of iterations) is still dramatically decreased due to the notable reduction in the number of iterations. Besides, in contrast to the method of [2], increasing the number of users $K$ does not slow down the convergence, so the proposed algorithm is scalable in large networks.

We also compare the proposed algorithm with the iterative algorithm of [20], which uses the approximate problem (33) but with an additional quadratic regularization term, cf. [29], where $\tau_k = 10^{-5}$ for all $k$, and decreasing stepsizes $\gamma^t = \gamma^t (1-d \gamma^t)$ where $d = 0.01$ is the so-called decreasing rate that controls the rate of decrease in the stepsize. We can see from Figure 2 that the convergence behavior of [20] is rather sensitive to the decreasing rate $d$. The choice $d = 0.01$ performs well when the number of transmit and receive antennas is 5 and 4, respectively, but it is no longer a good choice when the number of transmit and receive antenna increases to 10 and 8, respectively. A good decreasing rate $d$ is usually dependent on the problem parameters and no general rule performs equally well for all choices of parameters.

We remark once again that the complexity of each iteration of the proposed algorithm is very low because of the existence of a closed-form solution to the approximate problem (33), while the approximate problem proposed in [20] does not exhibit a closed-form solution and can only be solved iteratively. Specifically, it takes CVX (version 2.0 [32]) 21.1785 seconds (based on the dual approach [35] where $\lambda^*$ is found by bisection). Therefore, the overall complexity per iteration of the proposed algorithm is much lower than that of [20].

### B. Energy Efficiency Maximization in Massive MIMO Systems

In this subsection, we study the energy efficiency maximization problem in massive MIMO systems to illustrate the advantage of the relaxed convexity requirement of the approximate function $f(x; x^t)$ in the proposed iterative optimization approach: according to Assumption (A1), $f(x; x^t)$ only needs to exhibit the pseudo-convexity property rather than the convexity or strong convexity property that is conventionally required.
Consider the massive MIMO network with $K$ cells and each cell serves one user. The achievable transmission rate for each cell $k$ in the uplink can be formulated into the following general form:

$$r_k(p) = \log \left( 1 + \frac{w_{kk}p_k}{\sigma_k^2 + \phi_k p_k + \sum_{j \neq k} w_{kj}p_j} \right),$$ \hspace{1cm} (36)

where $p_k$ is the transmission power for user $k$, $\sigma_k^2$ is the covariance of the additive noise at the receiver of user $k$, while $\phi_k$ and $\{w_{kj}\}_{k,j}$ are positive constants that depend on the channel conditions only. In particular, $\phi_k p_k$ accounts for the hardware impairments, and $\sum_{j \neq k} w_{kj} p_j$ accounts for the interference from other users \[33\].

In 5G wireless communication networks, the energy efficiency is a key performance indicator. To address this issue, we look for the optimal power allocation that maximizes the energy efficiency:

$$\begin{align*}
\text{maximize} & \quad \frac{\sum_{k=1}^{K} r_k(p)}{P_c + \sum_{k=1}^{K} p_k} \\
\text{subject to} & \quad P_c \leq p \leq \bar{p},
\end{align*}$$ \hspace{1cm} (37)

where $P_c$ is a positive constant representing the total circuit power dissipated in the network, $p = (p_k)_{k=1}^{K}$ and $\bar{p} = (\bar{p}_k)_{k=1}^{K}$ specifies the lower and upper bound constraint, respectively.

Problem (37) is nonconvex and it is a NP-hard problem to find a globally optimal point \[5\]. Therefore we aim at finding respectively.

$$P = \{ p_k \}_{k=1}^{K} \text{ is constructed as follows: since } r_k(p) \text{ is concave in } p_k \text{ (shown in the right column of this page)},$$

and the partial concavity in the nonconcave function $\tilde{r}_k(p_k; p^t_k)$ is preserved in $\tilde{r}_k(p_k; p^t_k)$ \[39\], with $p^t_k$ fixed to be $p^t_k$. In this way, the partial concavity in the nonconcave function $\sum_{j=1}^{K} r_j(p)$ is preserved in $f(p; p^t)$.

Similarly, since $P_c + \sum_{k=1}^{K}$ in the denominator is linear in $p_k$, we only set $p_k = p^t_k$. Note that the division operator in the original problem (37) is kept in the approximate function $f(p; p^t)$ \[38\]. Although it will destroy the concavity (recall that a concave function divided by a linear function is no longer a concave function), the pseudo-concavity of $\tilde{r}_k(p_k; p^t_k)/(P_c + p_k + \sum_{j \neq k} p_j)$ is still preserved, as we show in two steps.

Step 1: The function $r_k(p_k, p^t_{-k})$ is concave in $p_k$. For the simplicity of notation, we define two constants $c_1 \triangleq w_{kk}/\phi_k > 0$ and $c_2 \triangleq (\sigma_k^2 + \sum_{j \neq k} w_{kj} p_j^t)/\phi_k > 0$. The first-order derivative and second-order derivative of $r_k(p_k, p^t_{-k})$ w.r.t. $p_k$ are

$$\begin{align*}
\nabla_{p_k} r_k(p_k, p^t_{-k}) &= \frac{1 + c_1}{(1 + c_1)p_k + c_2} - \frac{1}{p_k + c_2}, \\
\nabla_{p_k}^2 r_k(p_k, p^t_{-k}) &= \frac{(1 + c_1)p_k + c_2}{(1 + c_1)p_k + c_2}^2 + \frac{1}{(p_k + c_2)^2} = -2c_1c_2p_k(1 + c_1) - c_2^2c_1p_k^2 \quad \text{for } p_c \leq p_k \leq \bar{p}.
\end{align*}$$

Since $\nabla_{p_k} r_k(p_k, p^t_{-k}) < 0$ when $p \geq 0$, $r_k(p_k, p^t_{-k})$ is a concave function of $p_k$ in the nonnegative orthant $p_k \geq 0$ \[24\].

Step 2: Given the concavity of $r_k(p_k, p^t_{-k})$, the function $\tilde{r}_k(p_k; p^t_{-k})$ is concave in $p_k$. Since the denominator function of $\tilde{r}_k(p_k; p^t_{-k})$ is a linear (and thus convex) function of $p_k$, it follows from \[24\] Lemma 3.8 that $\tilde{r}_k(p_k; p^t_{-k})/(P_c + p_k + \sum_{j \neq k} p_j)_{p^t_{-k}}$ is pseudo-concave.

Then we verify that the gradient of the approximate function and that of the original objective function are identical at $p = p^t$. It follows that

$$\nabla_p f(p; p^t) \bigg|_{p = p^t} = \nabla_p \left( \frac{\tilde{r}_k(p_k; p^t_{-k})}{P_c + p_k + \sum_{j \neq k} p_j} \right) \bigg|_{p_k = p^t_k} = \frac{\sum_{j=1}^{K} r_j(p^t_{-j})}{(P_c + 1 + \sum_{j \neq k} p^t_j)^2}.$$ 

Therefore Assumption (A3) in Theorem \[3\] is satisfied. Assumption (A2) is also satisfied because both $\tilde{r}_k(p_k; p^t_{-k})$ and $p_k + P_c + \sum_{j \neq k} p^t_j$ are continuously differentiable for any $p^t_{-k} \geq 0$.

Given the approximate function \[38\], the approximate problem in iteration $t$ is thus

$$B p^t = \arg \max_{p \leq p^t \leq \bar{p}} \sum_{k=1}^{K} \tilde{r}_k(p_k; p^t_{-k}) \bigg|_{p_k = p^t_k}.$$ \hspace{1cm} (40)

Assumptions (A4) and (A5) can be proved to hold in a similar procedure shown in the previous example application. Since the objective function in \[37\] is nonconcave, it may not be computationally affordable to perform the exact line search. Instead, the successive line search can be applied to calculate the stepsize. As a result, the convergence of the proposed algorithm with approximate problem \[40\] and successive line
\[ p_k(\lambda_k^{t+1}) = \left[ \int_k \left( \phi_k - \frac{w_{kk}}{2(\phi_k + w_{kk})^2 - 4\phi_k (\pi_k(p^t) - \lambda_k^{t+1}(\int_k p^t) + 1)} \right) - \frac{1}{\zeta_k}, \right] \]

search follows from the same line of analysis used in the proof of Theorem \[3\].

The optimization problem in (40) can be decomposed into independent subproblems (41) that can be solved in parallel:

\[ \mathbb{B}_k p^t = \arg \max_{\rho_k \leq \rho_k \leq \rho_k} \frac{\bar{r}_k(p_k; p^t)}{P_c + p_k + \sum_{j \neq k} p_j^t}, \quad k = 1, \ldots, K, \]  

where \( \mathbb{B}_k p^t = (\mathbb{B}_k p^t)^K \). As we have just shown, the numerator function and the denominator function in (41) is concave and linear, respectively, so the optimization problem in (41) is a fractional programming problem and can be solved by the Dinkelbach’s algorithm \[33\] Algorithm 5: given \( \lambda_k^{t+1} \) (\( \lambda_k^{t+1} \) can be set to 0), the following optimization problem in iteration \( t + 1 \) is solved:

\[ p_k(\lambda_k^{t+1}) = \arg \max_{\rho_k \leq \rho_k \leq \rho_k} \frac{\bar{r}_k(p_k; p^t)}{P_c + p_k + \sum_{j \neq k} p_j^t}, \]  

where \( \bar{r}_k(p_k; p^t) \) is the numerator function in (41). The variable \( \lambda_k^{t+1} \) is then updated in iteration \( t + 1 \) as

\[ \lambda_k^{t+1} = \frac{\bar{r}_k(p_k(\lambda_k^{t+1}); p^t)}{P_c + p_k(p_k(\lambda_k^{t+1})) + \sum_{j \neq k} p_j^t}. \]  

It follows from the convergence properties of the Dinkelbach’s algorithm that

\[ \lim_{\tau \to \infty} p_k(\lambda_k^{t+1}) = \mathbb{B}_k p^t \]

at a superlinear convergence rate. Note that problem (42a) can be solved in closed-form, as \( p_k(\lambda_k^{t+1}) \) is simply the projection of the point that sets the gradient of the objective function in (42a) to zero onto the interval \([\rho_k, \rho_k]\). It can be verified that finding that point is equivalent to finding the root of a polynomial with order 2 and it thus admits a closed-form expression. We omit the detailed derivations and directly give the expression of \( p_k(\lambda_k^{t+1}) \) in (43) at the top of this page, where \( \pi_k(p^t) = \sum_{j \neq k} \nabla_{p_j} r_j(p^t) \) and \( \int_k p^t \) \( \triangleq \sigma_k^2 + \sum_{j \neq k} w_{kj} p_j^t \).

We finally remark that the approximate function in (43) is constructed in the same spirit as \[8\] \[9\] \[35\] by keeping as much concavity as possible, namely, \( r_k(p) \) in the numerator and \( P_c + \sum_{j=1}^K p_j \) in the denominator, and linearizing the non-concave functions only, namely, \( \sum_{j \neq k} r_j(p) \) in the numerator. Besides this, the denominator function is also kept. Therefore, the proposed algorithm is of a best-response nature and expected to converge faster than gradient based algorithms which linearizes the objective function \( \sum_{j=1}^K r_j(p)/(P_c + \sum_{j=1}^K p_j) \) in (37) completely. However, the convergence of the proposed algorithm with the approximate problem given in (40) cannot be derived from existing works, since the approximate function presents only a weak form of convexity, namely, the pseudo-convexity, which is much weaker than those required in state-of-the-art convergence analysis, e.g., uniform strong convexity in \[8\].

**Simulations.** The number of antennas at the BS in each cell is \( M = 50 \), and the channel from user \( j \) to cell \( k \) is \( h_{kj} \in \mathbb{C}^{M \times 1} \). We assume a similar setup as \[33\]: \( w_{kk} = |h_{kj}h_{kk}^*|^2, w_{kj} = |h_{kj}h_{kj}^*|^2 + \epsilon h_{kj}^2 D_j h_{kj} \) for \( j \neq k \) and \( \phi_k = ch_{kj}^2 D_j h_{kk} \), where \( \epsilon = 0.01 \) is the error magnitude of hardware impairments at the BS and \( D_j = \text{diag}(\{|h_{jj}(m)|^2\}_{m=1}^M) \). The noise covariance \( \sigma_k^2 = 1 \), and the hardware dissipated power \( p_c \) is 10dBm, while \( p_k \) is -10dBm and \( \bar{p}_k \) is 10dBm for all users. The benchmark algorithm is \[33\] Algorithm 1, which successively maximizes the following lower bound function of the objective function in (37), which is tight at \( p = p^t \):

\[ \max \left( P_c + \sum_{k=1}^K b_k + \frac{\sum_{k=1}^K \log w_{kk} \sum_{k=1}^K \log w_{kj} \sigma_k^2}{P_c + \sum_{k=1}^K \log w_{kj} \sigma_k^2} \right) \]

subject to \( \log(p_k) \leq q_k \leq \log(p_k), k = 1, \ldots, K, \) (44)

where

\[ a_k^t \triangleq \frac{\sin r_k(p^t)}{1 + \sin r_k(p^t)}, \]

\[ b_k^t \triangleq \log(1 + \sin r_k(p^t)) - \frac{\sin r_k(p^t)}{1 + \sin r_k(p^t)} \log(\sin r_k(p)) \]

and

\[ \sin r_k(p) \triangleq \frac{w_{kk} p_k^t}{\sigma_k^2 + \phi_k p_k + \sum_{j \neq k} w_{kj} p_j}. \]

Denote the optimal variable of (44) as \( q^t \) (which can be found by the Dinkelbach’s algorithm); then the variable \( p \) is updated as \( p^{t+1} = e^{q^t} \) for all \( k = 1, \ldots, K \). We thus coin \[33\] Algorithm 1 as the successive lower bound maximization (SLBM) method.

In Figure 4, we compare the convergence behavior of the proposed method and the SLBM method in terms of both the number of iterations (the upper subplots) and the CPU time (the lower subplots), for two different number of users: \( K = 10 \) in Figure 4(a) and \( K = 50 \) in Figure 4(b). It is obvious that the convergence speed of the proposed algorithm in terms of the number of iterations is comparable to that of the SLBM method. However, we remark that the approximate problem (40) of the proposed algorithm is superior to that of the SLBM method in the following aspects:

Firstly, the approximate problem of the proposed algorithm consists of independent subproblems that can be solved in parallel, cf. (41), while each subproblem has a closed-form
solution, cf. \cite{42,43}. However, the optimization variable in the approximate problem of the SLBM method \cite{44} is a vector \( q \in \mathbb{R}^{K \times 1} \) and the approximate problem can only be solved by a general purpose solver.

In the simulations, we use the Matlab optimization toolbox to solve \cite{44} and the iterative update specified in \cite{42,43} to solve \cite{40}, where the stopping criterion for \cite{42} is \( \| A \|_\infty \lesssim 10^{-5} \). The upper subplots in Figure 4 show that the numbers of iterations required for convergence are approximately the same for the SLBM method when \( K = 10 \) in Figure 3 (a) and when \( K = 50 \) in Figure 3 (b). However, we see from the lower subplots in Figure 4 that the CPU time of each iteration of the SLBM method is dramatically increased when \( K \) is increased from 10 to 50. On the other hand, the CPU time of the proposed algorithm is not notably changed because the operations are parallelizable \cite{44} and the required CPU time is thus not affected by the problem size.

Secondly, since a variable substitution \( q_k = e^{p_k} \) is adopted in the SLBM method (we refer to \cite{33} for more details), the lower bound constraint \( P_k = 0 \) (which corresponds to \( q_k = -\infty \)) cannot be handled by the SLBM method numerically. This limitation impairs the applicability of the SLBM method in many practical scenarios.

\subsection*{C. LASSO}

In this subsection, we study the LASSO problem to illustrate the advantage of the proposed line search method for nondifferentiable optimization problems.

LASSO is an important and widely studied problem in

\footnote{By stacking the \( p_k(\lambda^t_k) \)'s into the vector form \( p(\lambda^t) = (p_k(\lambda^t_k))_{k=1}^K \) we can see that only element wise operations between vectors and matrix vector multiplications are involved. The simulations on which Figure 4 are based are not performed in a real parallel computing environment with \( K \) processors, but only make use of the efficient linear algebraic implementations available in Matlab which already implicitly admits a certain level of parallelism.}

sparse signal recovery \cite{11,12,36,37}:

\[
\begin{aligned}
\text{minimize} & \quad \frac{1}{2} \| A x - b \|_2 + \mu \| x \|_1, \\
\end{aligned}
\]

where \( A \in \mathbb{R}^{N \times K} \) (with \( N \ll K \)), \( b \in \mathbb{R}^{K \times 1} \) and \( \mu > 0 \) are given parameters. Problem \cite{45} is an instance of the general problem structure defined in \cite{2} with the following decomposition:

\[
\begin{aligned}
f(x) & \triangleq \frac{1}{2} \| A x - b \|_2^2, \quad \text{and} \quad g(x) \triangleq \mu \| x \|_1. \\
\end{aligned}
\]

Problem \cite{45} is convex, but its objective function is nondifferentiable and it does not have a closed-form solution. To apply Algorithm 2 the scalar decomposition \( x = (x_k)_{k=1}^K \) is adopted. Recalling \cite{22} and \cite{29}, the approximate problem is

\[
\mathbb{B}x^t = \arg \min_x \{ \sum_{k=1}^K f(x_k, x^t_k) + g(x) \}. \\
\]

Note that \( g(x) \) can be decomposed among different components of \( x \), i.e., \( g(x) = \sum_{k=1}^K g(x_k) \), so the vector problem \cite{47} reduces to \( K \) independent scalar subproblems that can be solved in parallel:

\[
\mathbb{B}_k x^t = \arg \min_{x_k} \{ f(x_k, x^t_{-k}) + g(x_k) \}
\]

where \( d_k(A^T A) \) is the \( k \)-th diagonal element of \( A^T A \), \( S_a(b) \triangleq | b - a |^+ = (b - a)^+ \) is the so-called soft-thresholding operator \cite{37} and

\[
r(x) \triangleq d(A^T A) \circ x - A^T (Ax - b), \\
\]

or more compactly:

\[
\mathbb{B}x^t = (\mathbb{B}_k x^t)_{k=1}^K = d(A^T A)^{-1} \circ S_{\mu A} (r(x^t)).
\]
Thus the update direction exhibits a closed-form expression. The stepsize based on the proposed exact line search \((49)\) is
\[
\gamma_t = \arg \min_{0 \leq \gamma \leq 1} \left\{ f(x^t + \gamma(Bx^t - x^t)) + \gamma(g(Bx^t) - g(x^t)) \right\}
\]
\[
= \arg \min_{0 \leq \gamma \leq 1} \left\{ \frac{1}{2} \|A(x^t + \gamma(Bx^t - x^t)) - b\|^2_2 + \mu \gamma \frac{1}{1 - \gamma} \right\}
\]
\[
= -\frac{(Ax^t - b)^T A(Bx^t - x^t)}{(A(Bx^t - x^t))^T (A(Bx^t - x^t))} \cdot \frac{1}{\gamma^0},
\]
(50)

The exact line search consists in solving a convex quadratic optimization problem with a scalar variable and a bound constraint, so the problem exhibits a closed-form solution (50). Therefore, both the update direction and stepsize can be calculated in closed-form. We name the proposed update (49)-(50) as Soft-Thresholding with Exact Line search Algorithm (STELA).

The proposed update (49)-(50) has several desirable features that make it appealing in practice. Firstly, in each iteration, all elements are updated in parallel based on the nonlinear best-response (49). On the one hand, the term \(Ax^t - b\) is already available from \((51)\)\(^3\) and the direction of the signaling exchange. On the other hand, the term \(\gamma x^t \) is also required for the computation of \((Ax^t - b)\) as it can alternatively be computed as:
\[
Ax^{t+1} - b = A(x^t + \gamma(Bx^t - x^t)) - b
\]
\[
= (Ax^t - b) + \gamma A(Bx^t - x^t),
\]
(51)

The decompositions of the local processors as local processors and the central processor involved in (49) and (50) can also be implemented by a parallel architecture without a central processor. In this case, the signaling is exchanged mutually between every two of the local processors, but the analysis is similar and the conclusion to be drawn remains same: the proposed exact line search (50) does not incur additional signaling compared with predetermined stepsizes.

The convergent speed is generally faster than BCD (39) or the gradient-based update (40). Secondly, the proposed exact line search not only yields notable progress in each iteration but also enjoys an easy implementation given the closed-form gradient-based update (40). This is in the same spirit as (19, 38) and the elements are updated in parallel based on the nonlinear best-response (49)\(^3\). On the one hand, all the stepsize (50) does not incur any additional matrix-vector multiplications, but only affordable vector-vector multiplications.

Signaling exchange. When \(A\) cannot be stored and processed by a centralized processing unit, a parallel architecture can be employed. Assume there are \(P + 1\) \((P \geq 2)\) processors.
we observe that the exact line search [50] does not incur any additional signaling compared to that of predetermined step sizes (e.g., constant and decreasing step sizes), because the signaling exchange in S2.1-S2.2 has also to be carried out in the computation of $A^n x^n+1 - b$ in S3.2, cf. (51).

We finally remark that the proposed successive line search can also be applied and exhibits a closed-form expression as well. However, since the exact line search yields faster convergence, we omit the details at this point.

**Simulations.** We first compare in Figure 6 the proposed algorithm STELA with FLEXA [19] in terms of the error criterion $e(x^t)$ defined as:

$$ e(x^t) \triangleq ||\nabla f(x^t) - [\nabla f(x^t) - x^t]_{\mu,1}||_2. $$

Note that $x^*$ is a solution of (45) if and only if $e(x^*) = 0$ [23]. FLEXA is implemented as outlined in [19], however, the selective update scheme [19] is not implemented in FLEXA because it is also applicable for STELA and it cannot eliminate the slow convergence and sensitivity of the decreasing stepsize. We also remark that the stepsize rule for FLEXA is $\gamma^{t+1} = \gamma^t (1 - \min(1, 10^{-1}/e(x^t))) \delta^{t}$ [19], where $d$ is the decreasing rate and $\gamma^0 = 0.9$. The code and the data generating the figure can be downloaded online [41].

Note that the error $e(x^t)$ plotted in Figure 6 does not necessarily decrease monotonically while the objective function $f(x^t) + g(x^t)$ always does. This is because STELA and FLEXA are descent direction methods. For FLEXA, when the decreasing rate is low ($d = 10^{-1}$), no improvement is observed after 100 iterations. As a matter of fact, the stepsize in those iterations is so large that the function value is actually dramatically increased, and thus the associated iterations are discarded in Figure 6. A similar behavior is also observed for $d = 10^{-3}$, until the stepsize becomes sufficiently small. When the stepsize is quickly decreasing ($d = 10^{-4}$), although improvement is made in all iterations, the asymptotic convergence speed is slow because the stepsize is too small to make notable improvement. For this example, the choice $d = 10^{-2}$ performs well, but the value of a good decreasing rate depends on the parameter setup (e.g., $A$, $b$ and $\mu$) and no general rule performs equally well for all choices of parameters. By comparison, the proposed algorithm STELA is fast to converge and exhibits stable performance without requiring any parameter tuning.

We also compare in Figure 7 the proposed algorithm STELA with other competitive algorithms in literature: FISTA [57], ADMM [12], GreedyBCD [42] and SpaRSA [43]. We simulated GreedyBCD of [42] because it exhibits guaranteed convergence. The dimension of $A$ is $2000 \times 4000$ (the left column of Figure 7) and $5000 \times 10000$ (the right column). It is generated by the Matlab command `randn` with each row being normalized to unity. The density (the proportion of nonzero elements) of the sparse vector $x_{true}$ is 0.1 (the upper row of Figure 7), 0.2 (the middle row) and 0.4 (the lower row). The vector $b$ is generated as $b = Ax_{true} + e$ where $e$ is drawn from an i.i.d Gaussian distribution with variance $10^{-4}$. The regularization gain $\mu$ is set to $\mu = 0.1 \| A^T b \|_\infty$ which allows $x_{true}$ to be recovered to a high accuracy [43].

The simulations are carried out under Matlab R2012a on a PC equipped with an operating system of Windows 7 64-bit Home Premium Edition, an Intel i5-3210 2.50GHz CPU, and a 8GB RAM. All of the Matlab codes are available online [41]. The comparison is made in terms of CPU time that is required to reach a given error bound $E(x^t) \leq 10^{-6}$ is reached or the maximum number of iterations, namely, 2000, is reached. The running time consists of both the initialization stage required for preprocessing (represented by a flat curve) and the formal stage in which the iterations are carried out. For example, in the proposed algorithm STELA, $d(A^T A)$ is computed in the initialization stage since it is required in the iterative variable update in the formal stage, cf. (51). The simulation results are averaged over 20 instances.

We observe from Figure 7 that the proposed algorithm STELA converges faster than all competing algorithms. Some further observations are in order.

- The proposed algorithm STELA is not sensitive to the density of the true signal $x_{true}$. When the density is increased from 0.1 (left column) to 0.2 (middle column) and then to 0.4 (right column), the CPU time increases negligibly.

- The proposed algorithm STELA scales relatively well with the problem dimension. When the dimension of $A$ is increased from $2000 \times 4000$ (the left column) to $5000 \times 10000$ (the right column), the CPU time is only marginally increased.

- The initialization stage of ADMM is time consuming because of some expensive matrix operations as, e.g., $AA^T$, $(I + \frac{1}{\mu}AA^T)^{-1}$ and $A^T (I + \frac{1}{\mu}AA^T)^{-1} A$ ($c$ is a given positive constant). More details can be found in [12, Sec. 6.4]. Furthermore, the CPU time of the initialization stage of ADMM is increased dramatically when the dimension of $A$ is increased from $2000 \times 4000$ to $5000 \times 10000$.

- SpaRSA performs better when the density of $x_{true}$ is smaller, e.g., 0.1, than in the case when it is large, e.g., 0.2 and 0.4.

- The asymptotic convergence speed of GreedyBCD is
on the approximate function is that it is pseudo-convex. On the one hand, the relaxation of the assumptions on the approximate functions can make the approximate problems much easier to solve. We show by a counter-example that the assumption on pseudo-convexity is tight in the sense that when it is violated, the algorithm may not converge. On the another hand, the stepsize based on the exact/successive line search yields notable progress in each iteration. Additional structures can be exploited to assist with the selection of the stepsize, so that the algorithm can be further accelerated. The advantages and benefits of the proposed algorithm have been demonstrated using prominent applications in communication networks and signal processing, and they are also numerically consolidated. The proposed algorithm can readily be applied to solve other problems as well, such as portfolio optimization [10].

APPENDIX A
PROOF OF PROPOSITION

Proof: i) Firstly, suppose $y$ is a stationary point of (1); it satisfies the first-order optimality condition:

$$
\nabla f(y)^T (x - y) \geq 0, \forall x \in \mathcal{X}.
$$

Using Assumption (A3), we get

$$
\nabla \tilde{f}(y; y)^T (x - y) \geq 0, \forall x \in \mathcal{X}.
$$

Since $\tilde{f}(\bullet; y)$ is pseudo-convex, the above condition implies

$$
\tilde{f}(x; y) \geq \tilde{f}(y; y), \forall x \in \mathcal{X}.
$$

That is, $\tilde{f}(y; y) = \min_{x \in \mathcal{X}} \tilde{f}(x; y)$ and $y \in \mathcal{S}(y)$.

Secondly, suppose $y \in \mathcal{S}(y)$. We readily get

$$
\nabla f(y)^T (x - y) = \nabla \tilde{f}(y; y)^T (x - y) \geq 0, \forall x \in \mathcal{X},
$$

where the equality and inequality comes from Assumption (A3) and the first-order optimality condition, respectively, so $y$ is a stationary point of (1).

ii) From the definition of $\mathcal{B}x$, it is either

$$
\tilde{f}(\mathcal{B}x; y) = \tilde{f}(y; y),
$$

or

$$
\tilde{f}(\mathcal{B}x; y) < \tilde{f}(y; y).
$$

If (55a) is true, then $y \in \mathcal{S}(y)$ and, as we have just shown, it is a stationary point of (1). So only (55b) can be true. We know from the pseudo-convexity of $\tilde{f}(x; y)$ in $x$ (cf. Assumption (A1)) and (55b) that $\mathcal{B}x \neq y$ and

$$
\nabla \tilde{f}(y; y)^T (\mathcal{B}x - y) = \nabla f(y)^T (\mathcal{B}x - y) < 0,
$$

where the equality comes from Assumption (A3).

APPENDIX B
PROOF OF THEOREM

Proof: Since $\mathcal{B}x^t$ is the optimal point of (8), it satisfies the first-order optimality condition:

$$
\nabla \tilde{f}(\mathcal{B}x^t; x^t)^T (x - \mathcal{B}x^t) \geq 0, \forall x \in \mathcal{X}.
$$

If (55a) is true, then $x^t \in \mathcal{S}(x^t)$ and it is a stationary point of (1) according to Proposition (1)(i). Besides, it follows from

V. CONCLUDING REMARKS

In this paper, we have proposed a novel iterative algorithm based on convex approximation. The most critical requirement

\[ \text{minimize} \quad \|x\|_1 \quad \text{subject to} \quad Ax = b. \]

To adapt STELAFfor the BP problem, we use the augmented Lagrangian approach [13, 45]:

\[
\begin{align*}
x^{t+1} &= \|x\|_1 + (\lambda^t)^T (Ax - b) + \frac{c^t}{2} \|Ax - b\|_2^2, \\
\lambda^{t+1} &= \lambda^t + c^t (Ax^{t+1} - b),
\end{align*}
\]

where $c^{t+1} = \min(2c^t, 10^2)$ ($c^0 = 10/\|A^\top b\|_\infty$), $x^{t+1}$ is computed by STELA and this process is repeated until $\lambda^t$ converges. The numerical results summarized in [46] show that, although STELA must be called multiple times before the Lagrange multiplier $\lambda$ converges, the proposed algorithm for BP based on STELA is very competitive in terms of running time and robust in the sense that it solved all problem instances in the test platform database.
(54) (with \( x = Bx^t \) and \( y = x^t \)) that \( \nabla f(x^t)^T(Bx^t - x^t) \geq 0. \) Note that equality is actually achieved, i.e.,
\[
\nabla f(x^t)^T(Bx^t - x^t) = 0
\]
because otherwise \( Bx^t - x^t \) would be an ascent direction of \( f(x; x^t) \) at \( x = x^t \) and the definition of \( Bx^t \) would be contradicted. Then from the definition of the successive line search, we can readily infer that
\[
\nabla f(x^t)^T(Bx^t - x^t) = 0
\]
(58)

It is easy to see (58) holds for the exact line search as well. If \( 55b \) is true, \( x^t \) is not a stationary point and \( Bx^t - x^t \) is a strict descent direction of \( f(x) \) at \( x = x^t \) according to Proposition 1 (ii). \( f(x) \) is strictly decreased because \( y \) is updated at \( x^t \) along the direction \( Bx^t - x^t \). From the definition of the successive line search, there always exists a \( \gamma \) such that \( 0 < \gamma \leq 1 \) and
\[
f(x^{t+1}) = f(x^t + \gamma(Bx^t - x^t)) < f(x^t)
\]
(59)

This strict decreasing property also holds for the exact line search because it is the stepsize that yields the largest decrease, which is always larger than or equal to that of the successive line search.

We know from (58) and (59) that \( \{f(x^t)\} \) is a monotonically decreasing sequence and it thus converges. Besides, for any two (possibly different) convergent subsequences \( \{x^t\}_{t \in T_1} \) and \( \{x^t\}_{t \in T_2} \), the following holds:
\[
\lim_{t \to \infty} f(x^t) = \lim_{T_1 \ni t \to \infty} f(x^t) = \lim_{T_2 \ni t \to \infty} f(x^t).
\]
(60)

Now consider any convergent subsequence \( \{x^t\}_{t \in T} \) with limit point \( y \), i.e., \( \lim_{T \ni t \to \infty} x^t = y \). To show that \( y \) is a stationary point, we first assume the contrary: \( y \) is not a stationary point. Since \( f(x; x^t) \) is continuous in both \( x \) and \( x^t \) by Assumption (A2) and \( \{Bx^t\}_{t \in T} \) is bounded by Assumption (A5), it follows from (25) Th. 1] that there exists a sequence \( \{Bx^t\}_{t \in T} \) with \( T \subseteq T \) such that it converges and \( \lim_{T \ni t \to \infty} Bx^t \in S(y) \). Since both \( f(x) \) and \( \nabla f(x) \) are continuous, applying (25) Th. 1] again implies there is a \( T \) such that \( T \subseteq T \subseteq T \) and \( \{x^t\}_{T \ni t \to \infty} \) converges to \( y' \) defined as:
\[
y' = y + \rho(\nabla f(y) - y),
\]
where \( \rho \) is the stepsize when either the exact or successive line search is applied to \( f(y) \) along the direction \( \nabla f(y) - y \). Since \( y \) is not a stationary point, it follows from (59) that \( f(y') < f(y) \), but this would contradict (60). Therefore \( y \) is a stationary point, and the proof is completed.

**APPENDIX C**

**PROOF OF THEOREM 3**

Proof: We first need to show that Proposition (1) still holds.
(i) We prove \( y \) is a stationary point of (4) if and only if \( y_k \in \arg \min_{x_k \in X_k} f(x_k, y_k) \) for all \( k = 1, \ldots, K \).

Suppose \( y \) is a stationary point of (4), it satisfies the first-order optimality condition:
\[
\nabla f(y)^T(x - y) = \sum_{k=1}^K \nabla f_k(y)^T(x_k - y_k) \geq 0, \forall x \in X,
\]
and it is equivalent to
\[
\nabla f_k(y)^T(x_k - y_k) \geq 0, \forall x_k \in X_k.
\]
Since \( f(x) \) is pseudo-convex in \( x_k \), the above condition implies \( f(y_k, y_k) = \min_{x_k \in X_k} f(x_k, y_k) \) for all \( k = 1, \ldots, K \).

Suppose \( y_k \in \arg \min_{x_k \in X_k} f(x_k, y_k) \) for all \( k = 1, \ldots, K \). The first-order optimality conditions yields
\[
\nabla f_k(y)^T(x_k - y_k) \geq 0, \forall x_k \in X_k.
\]
Adding the above inequality for all \( k = 1, \ldots, K \) yields
\[
\nabla f(y)^T(x - y) \geq 0, \forall x \in X.
\]
Therefore, \( y \) is a stationary point of (4).

(ii) We prove that if \( y \) is not a stationary point of (4), then \( \nabla f(y)^T(\nabla f(y) - y) < 0 \).

It follows from the optimality of \( B \) that
\[
f(B_ky, y_k) \leq f(x_k, y_k),
\]
and
\[
\nabla f_k(B_ky, y_k)^T(x_k - B_ky) \geq 0, \forall x_k \in X_k.
\]
(61)

Firstly, there must exist an index \( j \) such that
\[
f(B_jy, y_j) < f(y_j, y_j),
\]
(62)

otherwise \( y \) would be a stationary point of (4). Since \( f(x) \) is pseudo-convex in \( x_k \) for \( k = 1, \ldots, K \), it follows from (62) that
\[
\nabla f_j(y)^T(\nabla f_jy - y_j) < 0.
\]
(63)

Secondly, for any index \( k \) such that \( f(B_ky, y_k) = f(x_k, y_k) \), \( y_k \) minimizes \( f(x_k, y_k) \) over \( x_k \in X_k \) and
\[
\nabla f(B_ky, y_k)^T(x_k - y_k) \geq 0, \forall x_k \in X.
\]
Setting \( x_k = B_ky \) yields
\[
\nabla f_k(B_ky, y_k)^T(B_ky - y_k) \geq 0.
\]
(64)

Similarly, setting \( x_k = y_j \) in (61) yields
\[
\nabla f(B_ky, y_k)^T(B_ky - y_k) \geq 0.
\]
(65)

Adding (64) and (65), we can infer that \( \nabla f(y) - \nabla f_k(B_ky, y_k)^T(y_k - B_ky) \geq 0 \). Therefore, we can rewrite (65) as follows
\[
0 \leq \nabla f(B_ky, y_k)^T(y_k - B_ky)
\]
\[
= \nabla f_k(y_k, y_k)^T(y_k - B_ky).
\]
and thus

\[ \nabla_k f(y)(B_k y - y_k) \leq -\left( \nabla_k f(B_k y, y_k) - \nabla_k f(y) \right)^T (B_k y - y_k) \leq 0. \quad (66) \]

Adding (63) and (66) over all \( k = 1, \ldots, K \) yields

\[ \nabla_j f(y)^T (B_j y - y) = \sum_{k=1}^K \nabla_k f(y)^T (B_k y - y_k) < 0. \]

That is, \( B_j y - y \) is a descent direction of \( f(x) \) at the point \( y \).

The proof of Theorem 2 can then be used verbatim to prove the convergence of the algorithm with the approximate problem (31) and the exact/successive line search.
