Abstract

Present data prefer a large but non-maximal 2–3 mixing in the lepton sector. We argue that this value, in connection with $\sin \theta_{13} \simeq 0.15$, is the generic outcome of minimal flavour structures. We present a few different incarnations of this statement, in terms of lepton mass matrices depending on a small number of parameters, that can be justified by discrete flavour symmetries. We also propose a general procedure to study the correlation between $\theta_{23}$, the absolute scale and ordering of the neutrino masses, and the leptonic CP-violating phases.

1 Introduction

Flavour models aim to explain the observed pattern of fermion masses and mixing, in terms of some dynamical mechanism for flavour symmetry breaking. In the quark sector the regular hierarchy of masses and mixing angles definitely points to an underlying dynamics, that unfortunately may be difficult to probe directly. In the lepton sector, in the last 15 years neutrino oscillation experiments led to a tremendous improvement in the knowledge of the neutrino masses and mixing. Still a few important observables in the neutrino mass matrix are presently unmeasured, and one expects substantial improvements in the next decade.

A reasonable (but not exclusive) figure of merit for flavour models is the ability to predict a set of observables in terms of a smaller set of parameters. Speculations on “symmetric” values of the lepton observables (maximal or zero mixing angles, vanishing or degenerate mass eigenvalues, . . . ) have been pursued, and recent indications against these extreme values may seem to disfavour most theoretical proposals. However, one should keep in mind that minimal flavour structures do not imply extreme values of the observables, as we will show in a few explicit examples.
Oscillation experiments are sensitive, in particular, to the three lepton mixing angles. Before 2012, only $\theta_{12}$ and $\theta_{23}$ were known to be non-zero and large. One year later, the situation changed dramatically: the $1 - 3$ mixing angle $\theta_{13}$ has been precisely measured by reactor experiments [1] to be of the order of the Cabibbo angle and, given the precise determination of $\theta_{12}$ by solar experiments, the largest uncertainty pertains to $\theta_{23}$, that could significantly deviate from the maximal value. Indeed, global fits [2, 3] favour non-maximal $2 - 3$ mixing at the $2\sigma$ level (an effect driven by accelerator neutrino data), with a slight preference for $\theta_{23} < \pi/4$ in the case of normal ordering of the mass spectrum (as a consequence of atmospheric neutrino data). Before the measurement of a non-zero $\theta_{13}$, a considerable theoretical effort was invested in explaining a tri-bi-maximal pattern for the lepton mixing angles (see Ref. [4] for a review). In the latter approach, one needs now to correct significantly the leading-order predictions, by taking into account a number of sub-leading effects. After the measurement of a relatively large $\theta_{13}$, several flavour models have been proposed, that predict a non-zero value of $\theta_{13}$ at leading order [5, 6].

In this paper we would like to reconsider the lepton flavour structure in the light of the up-to-date knowledge of the mixing angles. Our focus will be on the non-maximal value of $\theta_{23}$ and on the search for the minimal flavour patterns that lead to such value. Rather than elaborating on general aspects of model-building with flavour symmetries, we will modestly propose a few simple scenarios that make some definite predictions. In fact, as the number of technical assumptions in the models is reduced, we will find that the values of $\theta_{12}$ and $\theta_{13}$ point to a deviation from maximal $\theta_{23}$ of the required size.

The predictions of flavour models are meant to motivate the future experimental program, including precise neutrino oscillation experiments, as well as measurements of the absolute neutrino mass scale and of the neutrino-less double-beta ($0\nu2\beta$) decay rates. In this spirit, we will consider lepton mass matrices that depend on a small number of parameters, and we will propose a systematic procedure to illustrate the associated predictions (section 2). We focus our attention on the mass matrix structures where the $2 - 3$ mixing angle is predicted close to the present best fit value, $\sin^2\theta_{23} \simeq 0.4$ or $\sin^2\theta_{23} \simeq 0.6$. We will demonstrate that they can be associated to simple, spontaneously broken, discrete flavour symmetries. One scenario corresponds to neutrino mass matrices with two zero entries and two non-zero entries equal to each other (section 3). A second scenario resorts to the sum of two contributions to the neutrino mass matrix: a flavour off-diagonal term, plus a flavour-universal one (section 4). Finally, the minimal model with a flavour symmetry broken by a flavon doublet is presented (section 5). These models allow, in particular, to correlate the $2 - 3$ mixing octant with the value of the CP violating phase $\delta$, as well as with the ordering of the neutrino mass spectrum (normal or inverse), thus motivating the experimentalists to solve the degeneracies that affect the long-baseline oscillation program [7].
2 From the neutrino mass matrix to the observables

We assume the Standard Model is extended to include a Majorana mass matrix for the three active neutrinos. The nine flavour observables in the neutrino sector can be currently divided in two groups. On the one hand, four physical parameters are precisely determined (with less than 10% uncertainty):

\[ p_a = \Delta m^2_{21}, \ |\Delta m^2_{31}|, \ \theta_{12}, \ \theta_{13}, \]

with the sign of \( \Delta m^2_{31} \) still unknown. On the other hand, five parameters are at most weakly constrained. The mixing angle \( \theta_{23} \) can largely depart from the maximal value, \( 0.34 \lesssim \sin^2 \theta_{23} \lesssim 0.67 \) at 3\( \sigma \) [2,3]. The lightest neutrino mass \( m_{\text{light}} \) can vary between zero and a few tenths of an electronvolt, the upper bound depending on the combination of cosmological data; we will assume a conservative limit, \( \sum_i m_i \lesssim 0.5 \) eV at 95% C.L. [8]. The Dirac-type CP-violating phase \( \delta \) is unknown and can lie anywhere in the interval \( [0, 2\pi) \), with some range of values already disfavoured at the 1\( \sigma \) level by global fits of oscillation data [2,3]. Finally, the two Majorana-type CP-violating phases are unknown as well. The only experimentally accessible quantity sensitive to the latter two phases is the effective 0\( \nu \)2-\( \beta \)-decay mass parameter \( m_{ee} \), which is experimentally known to be smaller than a few tenths of an electronvolt; we will adopt the upper bound \( m_{ee} \lesssim 0.38 \) eV at 90% C.L., coming from the EXO-200 experiment [9]. The central objective of the present and future experimental program is the precise determination of these four observables (together with the sign of \( \Delta m^2_{31} \)):

\[ x_i = \theta_{23}, \ m_{\text{light}}, \ \delta, \ m_{ee} . \]

Flavour symmetry models may predict special structures of the neutrino mass matrix \( M_\nu \) (in the basis where the charged lepton mass matrix \( M_\ell \) is diagonal), that depend on few parameters, and therefore predict correlations between the observables. In particular, four real parameters of \( M_\nu \) can be fixed to reproduce the observed values of the \( p_a \)'s, up to their small experimental uncertainties. If \( M_\nu \) depends on four (or less) parameters only, then one can derive a unique prediction for all the other observables, \( x_i^\pm = x_i^\pm (p_a) \), where the superscript denotes the sign of \( \Delta m^2_{31} \). In this case the precise measurement of one \( x_i \) can rule out the given matrix structure. If \( M_\nu \) depends on five parameters, then it is sufficient to specify the value of an additional observable \( x_j \) to predict the values of the other three, \( x_i^\pm = x_i^\pm (x_j, p_a), \ i \neq j \). Such matrix structures can be tested in general by measuring with sufficient precision two \( x_i \)'s. And so on and so forth.

If the procedure to compute \( x_i^\pm \) is carried out analytically, then it provides the full set of predictions for a given form of \( M_\nu \). In general such procedure requires some tedious algebraic manipulations, but the advantage is to avoid a numerical sampling of the allowed range for the input
parameters, or an expansion in powers of some small parameter, with the associated ambiguities.

Let us illustrate our method for a specific matrix structure that will be useful in the following, and that depends on five physical parameters:

$$M_\nu = \begin{pmatrix} a & b & c \\ b & 0 & d \\ c & d & 0 \end{pmatrix}.$$  \hspace{1cm} (3)

The entries $a$, $b$, $c$ and $d$ are in general complex, but three phases can be absorbed in a redefinition of the three neutrino wavefunctions. Thus, there is a one-to-one correlation between the sought-after observables $x_i$'s. The six functions $x_i^+ = x_i^+(x_j)$ for $i \neq j$ are shown in Figures 1 and 2, for the case ‘+’ ($m_{\text{light}} = m_1$, normal ordering) and ‘−’ ($m_{\text{light}} = m_3$, inverse ordering), respectively. The procedure to derive $x_i^+(x_j)$ analytically is described in the Appendix, and it applies to any matrix $M_\nu$ with two zero entries. In principle one may find an analogue procedure for any structure of $M_\nu$ that depends on five parameters (see section 4 for a particularly interesting example).

As the matrix in Eq. (3) maintains the same structure under conjugation, for $\delta \leftrightarrow -\delta$ the other observables are unchanged, therefore in Figures 1 and 2 we need to display only the interval $[0,\pi]$ for $\delta$. This matrix structure is also invariant under the exchange of the 2nd and 3rd rows and columns. This corresponds to the following exchange in the values of the observables:

$$\theta_{23} \leftrightarrow \pi/2 - \theta_{23} \quad \text{and} \quad \delta \leftrightarrow \pi - \delta.$$  \hspace{1cm} (4)

Such relation can be clearly observed in the plots. In the case of inverse ordering, illustrated in Fig. 1, the $2-3$ mixing lies in the first (second) octant for $\cos \delta > 0$ ($< 0$). The curve $\delta(\theta_{23}, \rho_a)$ is well described, up to small corrections of order $\Delta m^2_{31}/\Delta m^2_{21}$, by the relation

$$\cos \delta \tan 2\theta_{23} \tan 2\theta_{12} \sin \theta_{13} \simeq 1.$$  \hspace{1cm} (5)

The mass spectrum can be quasi-degenerate or hierarchical, with a lower bound $m_3 \gtrsim 0.02$ eV, and $m_{ee} \simeq m_3$. The upper bound on $\sum_i m_i$ implies $\sin^2 \theta_{23} \lesssim 0.48$ with $\cos \delta \gtrsim 0.13$, or $\sin^2 \theta_{23} \gtrsim 0.52$ with $\cos \delta \lesssim -0.13$. In the case of normal ordering, illustrated in Fig. 2, the $2-3$ mixing is extremely close to maximal, the mass spectrum is quasi-degenerate, with $m_i \gtrsim 0.15$ eV. As a consequence, values of $\delta$ close to 0 or $\pi$ are predicted. The equality $m_{ee} \simeq m_i$ holds in very good approximation. The present upper bound on $\sum_i m_i$ almost rules out the normal ordering case. Our exact results are consistent with the analysis of the matrix in Eq. (3) performed in Ref. [11], where the correlations between the $x_i$'s were understood by a sequence of careful approximations.

In order to identify a possible flavour symmetry responsible for the mass matrix structure in Eq. (3), it is useful to inspect the size of the parameters
Figure 1: The correlations between $\sin^2 \theta_{23}$, $\delta$, $m_3$ (in eV) and $m_{ee}$ (in eV) for the neutrino mass matrix in Eq. (3), in the case of inverted ordering of the mass spectrum. The thick purple lines correspond to the best fit value of the parameters $p_a$’s in Eq. (1), while the purple shaded regions correspond to the $3\sigma$ allowed range for the $p_a$’s. The yellow bands are excluded by oscillation experiments. The green (blue) bands are excluded by the cosmological upper bound on $\sum m_i$ (by the EXO-200 upper bound on $m_{ee}$). These three exclusion bands are taken into account in all the six panels: the excluded portions of the best fit lines are dashed and the excluded portions of the $3\sigma$ regions are not shaded.
Figure 2: The same as in Fig. 1 but in the case of normal ordering.

$a, b, c, d,$ that are needed to reproduce the experimental data. Note that, once the four input values for the $p_a$'s are fixed, the mass matrix elements are fully determined as a function of one observable $x_j$. In Fig. 3 we show $m_{\alpha \beta} \equiv |(M_{\nu})_{\alpha \beta}|$ as a function of $\sin^2 \theta_{23}$, for $\alpha \beta = ee, e\mu, e\tau, \mu\tau$. One observes that the pair $m_{ee}$ and $m_{\mu\tau}$ is quasi-degenerate in the whole range of $\theta_{23}$, while the pair $m_{e\mu}$ and $m_{e\tau}$ becomes more and more degenerate as $\theta_{23}$ approaches the maximal value. Note also that, in the case of inverse ordering, the two pairs cross each other for some special values of $\theta_{23}$, that actually lie in the present $1\sigma$ preferred regions.
Figure 3: The absolute values $m_{\alpha \beta}$ (in eV) of the entries of the $M_\nu$ in Eq. (3), as a function of $\sin^2 \theta_{23}$, for the case of inverse (left-hand panel) and normal (right-hand panel) ordering. The thin solid blue line corresponds to $m_{ee}$, the thick dashed red line to $m_{\mu \tau}$, the thin dashed blue line to $m_{e\mu}$ and the thin dotted blue line to $m_{e\tau}$. The shaded bands are the same as in Fig. 1. The two pairs of vertical dashed lines limit the 1\(\sigma\) preferred region for $\theta_{23}$ in each octant.

3 A symmetry for zero and equal entries in the neutrino mass matrix

In the previous section we proposed a procedure to illustrate the phenomenological implications of a neutrino mass matrix depending on few parameters. From a theoretical point of view, one shall wonder whether the minimal viable matrix structures can be justified by a symmetry.

In this section we will focus on the matrix in Eq. (3) in the limit $b = d$, since it corresponds to two values of $\sin^2 \theta_{23}$ close to the presently preferred values in the first and in the second octant, as shown in Fig. 3. Taking

$$M_\nu = \begin{pmatrix} a & b & c \\ b & 0 & b \\ c & b & 0 \end{pmatrix},$$

and considering the 3\(\sigma\) allowed range for the parameters $p_a$’s, one finds two possible solutions:

$$\begin{cases} \sin^2 \theta_{23} = 0.40^{+0.02}_{-0.01} \\ \cos \delta = 0.59^{+0.12}_{-0.14} \\ m_{\text{light}} = m_3 = 0.037^{+0.001}_{-0.002} \text{eV} \\ m_{ee} = 0.036^{+0.002}_{-0.001} \text{eV} \end{cases} \quad \begin{cases} \sin^2 \theta_{23} = 0.62^{+0.03}_{-0.02} \\ \cos \delta = -0.75^{+0.15}_{-0.12} \\ m_{\text{light}} = m_3 = 0.0289^{+0.0002}_{-0.0001} \text{eV} \\ m_{ee} = 0.0284^{+0.0000}_{-0.0001} \text{eV} \end{cases}$$

(7)

At first sight it may seem arduous to justify the vanishing of two entries of $M_\nu$ together with the equality of two other entries, at the same time maintaining the charged lepton mass matrix $M_e$ diagonal. Here we will
illustrate the ingredients needed to achieve this result and build a representative flavour symmetry model. We remark that, no matter how elaborate such model may be, it provides the sharp predictions in Eq. (7) for the observables.

The search for the appropriate flavour symmetry goes as follows:

- The equality of the matrix entries $M_{e\mu}$ and $M_{\tau\mu}$ requires that the two lepton doublets $l_e$ and $l_\tau$ transform together under the symmetry, that is, they belong to a dimension-two irreducible representation (irrep) $2_l$, while $l_\mu$ is a flavour singlet $1_l$. In this way the two equal matrix entries can arise from a flavon doublet $\phi$, that is, a scalar field in a doublet irrep $2_\phi$, that acquires a vacuum expectation value (vev) in the direction $\langle \phi \rangle \propto (1,1)$.

- The tensor product $2_l \times 2_l$ must lead to a non-zero diagonal entry, $M_{ee} = a$, and a vanishing one, $M_{\tau\tau} = 0$. Some simple group theory leads to the conclusion that this tensor product must contract with an additional flavon doublet $\phi'$, with $\langle \phi' \rangle \propto (1,0)$. Since $\phi$ and $\phi'$ must contribute separately in the sector $2_l \times 1_l$ and $2_l \times 2_l$, the flavour group must provide two different doublet irreps, $2_\phi \neq 2_{\phi'}$.

- Finally, since $M_{\mu\mu}$ vanishes, the tensor product $1_l \times 1_l$ should not be invariant under the flavour symmetry.

The simplest group that satisfies these properties is the order-twelve quaternion group $Q_6$, also known as the double-dihedral group $D'_3$, that has two doublet irreps $2_1$ and $2_2$, plus four singlet irreps $1_i$, with in particular $1_3 \times 1_3 = 1_4 \times 1_4 = 1_2$, different from the invariant singlet $1_l$. For the relevant group properties and conventions, we refer to Ref. [10], that provides useful tools for the analysis of (double-)dihedral symmetries in general.

Let us begin from the neutrino sector, writing the Majorana mass term as $y^k_{ij} l_i l_j \phi_k (hh/\Lambda)$, where $h$ is the Higgs doublet and $\phi_k$ are the flavon fields that transform under $Q_6$ (we normalized $\phi_k$ to be dimensionless, that is, a scalar field over some cutoff scale). The lepton doublets and the flavons are assigned to the irreps of $Q_6$ in order to satisfy the above list of requirements,

\[
\begin{align*}
(l_e) & \sim 2_2, \quad (l_\mu) \sim 1_3, \quad (\phi_{1u}) \sim 2_1, \quad (\phi_{2u}) \sim 2_2.
\end{align*}
\]

Then, the $Q_6$-invariant Lagrangian has the form

\[
-\mathcal{L}_\nu = \left[ y_{e\tau} l_e l_\tau + \frac{1}{2} y_{ee} (l_e e \phi_{2u} + l_\tau e \phi_{2d}) + y_{e\mu} (l_e \phi_{1u} + l_\tau \phi_{1d}) l_\mu \right] \frac{hh}{\Lambda} + h.c.
\]

Taking $\langle \phi_1 \rangle = c_1 (1,1)$ and $\langle \phi_2 \rangle = c_2 (1,0)$, one obtains the neutrino mass matrix in Eq. (6), with $a = y_{ee} c_2 v^2/\Lambda$, $b = y_{e\mu} c_1 v^2/\Lambda$ and $c = y_{e\tau} v^2/\Lambda$.

The model works as long as $M_\ell$ is diagonal in the same basis. The charged lepton mass term can be written as $\lambda^k_{ij} l_i e^c_j \phi_k h^*$, where $e^c_j$ are the
charged lepton singlets and \( \varphi_k \) the flavons, in general different from those in the neutrino sector. With the assignment

\[
\begin{align*}
\begin{pmatrix} \mu^c \\ e^c \end{pmatrix} & \sim 2_1, \\
\begin{pmatrix} \varphi_{1u} \\ \varphi_{1d} \end{pmatrix} & \sim 2_1, \\
\begin{pmatrix} \varphi_{2u} \\ \varphi_{2d} \end{pmatrix} & \sim 2_2,
\end{align*}
\]

the \( Q_6 \)-invariant Lagrangian reads

\[
-\mathcal{L}_e = \left[ \lambda_e (l_e e^c \varphi_{1d} - l_\tau \mu^c \varphi_{1u}) + \lambda_{\mu} (\mu^c \varphi_{2u} + e^c \varphi_{2d}) \\
+ \lambda_{\tau} (l_\tau \varphi_{1d} + l_e \varphi_{1u}) \right] h^* + h.c. .
\]

For \( \langle \varphi_1 \rangle = c_1'(0, 1) \) and \( \langle \varphi_2 \rangle = c_2'(1, 0) \), the charged lepton mass matrix is diagonal, with \( m_e = \lambda_e c_1' v \), \( m_\mu = \lambda_\mu c_2' v \) and \( m_\tau = \lambda_\tau c_1' v \).

This completes the prove of existence of a minimal model leading to Eq. (6). Note that the flavour group \( Q_6 \) is entirely broken by the flavon vevs, both in the neutrino and in the charged lepton sector.

4 Off-diagonal plus universal neutrino masses

Here we propose another, remarkably simple structure of the neutrino mass matrix that depends on five physical parameters and predicts the preferred, non-maximal \( \theta_{23} \). We will justify this structure with a minimal flavour symmetry at the end of this section.

Our starting point is the so-called Zee mass matrix \([12, 13]\), with only off-diagonal entries,

\[
M'_\nu = \begin{pmatrix}
0 & a & b \\
a & 0 & c \\
b & c & 0
\end{pmatrix},
\]

(12)
in the basis where \( M_e \) is diagonal. The phases of \( a, b \) and \( c \) can be rotated away, thus there is no CP-violation and the leptonic mixing is described by a real orthogonal matrix \( R \), with \( M'_\nu = R \text{diag}(\lambda_1, \lambda_2, \lambda_3) R^T \). A simple way to extract a constraint on the mixing angles is to regard the three zero diagonal entries as a homogeneous system of three linear equations,

\[
\sum_j Z_{ij} \lambda_j = 0, \quad i = 1, 2, 3,
\]

(13)
where \( Z_{ij} = R_{ij}^2 \). In order to have a non-trivial solution, the matrix \( Z \) must be singular. The equation \( \det Z = 0 \) establishes a relation between the mixing angles,

\[
\frac{1}{\tan(2\theta_{12})} \frac{1}{\tan(2\theta_{23})} \frac{2(1 - 2 \sin^2 \theta_{13})}{\sin \theta_{13}(1 - 3 \sin^2 \theta_{13})} = \pm 1,
\]

(14)
where the positive (negative) sign corresponds to \( \theta_{23} < \pi/4 \) (\( \theta_{23} > \pi/4 \)) and \( \delta = 0 \) (\( \delta = \pi \)). Not surprisingly, this equation has been already derived in various ways in the literature (see e.g. Refs. \([14, 15]\)). Indeed, the
Figure 4: The predicted value of $\sin^2 \theta_{23}$ as a function of $\sin^2 \theta_{12}$ and $\sin^2 \theta_{13}$, for the off-diagonal neutrino mass matrix of Eq. (12). The green shaded band corresponds to the 1σ range for $\sin^2 \theta_{23}$ in the first octant (left-hand panel) and in the second octant (right-hand panel). The vertical (horizontal) band corresponds to the 3σ range for $\sin^2 \theta_{12}$ ($\sin^2 \theta_{13}$). Dashed lines are the best fit values of the mixing angles.

The corresponding prediction for $\theta_{23}$ fulfills with great accuracy the most recent oscillation data, as shown in Fig. 4. Taking the best fit values and the 3σ ranges for $\theta_{12}$ and $\theta_{13}$ from Ref. [3], Eq. (14) implies

$$\sin^2 \theta_{23} = 0.42^{+0.02}_{-0.04} \text{ or } 0.58^{+0.04}_{-0.02}.$$  \hspace{1cm} (15)

It is remarkable that these intervals roughly coincide with the 1σ preferred regions for $\theta_{23}$.

The Zee mass matrix is known to be unable to reproduce all current data [14, 16, 17]: it was shown that, if one fits the two neutrino mass squared differences, then the resulting mixing pattern is close to bi-maximal, which rules out the model. This is simply because the three parameters $a$, $b$ and $c$ are insufficient to accommodate the values of the four precisely measured observables $p_i$’s. In fact, the three zeroes on the diagonal imply Eq. (14) as well as two relations between the eigenvalues,

$$\lambda_1 + \lambda_2 + \lambda_3 = 0 \hspace{0.5cm} \text{and} \hspace{0.5cm} \lambda_1(\cos^2 \theta_{12} - \tan^2 \theta_{13}) = \lambda_2(\tan^2 \theta_{13} - \sin^2 \theta_{12}).$$ \hspace{1cm} (16)

Given the measured values of the mixing angles, the mass squared differences $\Delta m_{ij}^2 = \lambda_i^2 - \lambda_j^2$ are incompatible with data.

Now, the perfect prediction for $\theta_{23}$ makes us wonder whether the lepton mixing pattern is indeed determined by an off-diagonal mass term, while the neutrino mass eigenvalues are not. Then, the most natural extension of Eq. (12) is the addition of a universal mass term,

$$M_\nu = \begin{pmatrix} 0 & a & b \\ a & 0 & c \\ b & c & 0 \end{pmatrix} + d \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix},$$ \hspace{1cm} (17)
with \( d = |d|e^{i\chi} \) complex in general. This modification does not affect the mixing matrix, as long as \( a, b \) and \( c \) are real (or have the same phase). The neutrino mass eigenvalues are given by

\[
m_i = |\lambda_i + d|,
\]

and one is able to accommodate the two neutrino mass squared differences. In particular, we obtain a condition on the mixing angles that determines the ordering of the neutrino mass spectrum:

\[
\text{normal for } s_{12}^2 < \frac{s_{13}^2 + 1}{3}, \quad \text{inverse for } s_{12}^2 > \frac{s_{13}^2 + 1}{3}.
\]

The experimental values of \( \theta_{12} \) and \( \theta_{13} \) prefer normal ordering, with the inverse one only marginally allowed at 3\( \sigma \).

Note that the \( M_\nu \) in Eq. (17) depends on five physical parameters, but it behaves in a singular manner with respect to our general analysis of section 2: the four input parameters \( p_a \)'s fix \( a, b, c \) (or equivalently the three \( \lambda_i \)'s) and the product \( |d| \cos \chi \). Two output parameters are automatically determined by Eq. (14): \( \theta_{23} \) and \( \delta \) (equal to 0 or \( \pi \)). As \( d \) is in general complex, there is CP-violation, but only in the form of Majorana phases. The other two output parameters, \( m_{\text{light}} \) and \( m_{ee} \), depend on \( |d| \) and \( \cos \chi \) separately, and thus there is a non-trivial correlation between them, \( m_{ee} = m_{ee}(m_{\text{light}}, p_a) \), that is illustrated in Fig. 5. Since the product \( |d| \cos \chi \) is fixed by the \( p_a \)'s, there is a lower bound on \( m_{ee} \equiv |d| \), which translates into a lower bound on \( m_{\text{light}} \) too. In the case of normal ordering, taking into account the 3\( \sigma \) uncertainties on the \( p_a \)'s, we obtain

\[
m_1 \gtrsim 4.3 \times 10^{-2} \text{ eV}, \quad m_{ee} \gtrsim 2.1 \times 10^{-2} \text{ eV}.
\]

The inverse ordering is disfavoured by the cosmological bound on \( \sum m_i \).

Let us show that the matrix in Eq. (17) can be motivated by a minimal flavour symmetry. Clearly, the three lepton doublets shall transform in a triplet irrep of the flavour group. The smallest group with such an irrep is \( A_4 \), the alternating group of 4 objects (we adopt the conventions in Ref. [15]). The universal mass term is precisely the unique \( A_4 \)-invariant contribution to \( M_\nu \), while the off-diagonal mass term is generated by an \( A_4 \)-triplet flavon field \( (\phi_1, \phi_2, \phi_3) \):

\[
-L_\nu = \left[ \frac{1}{2} y_{\text{uni}} \sum_a l_a l_\alpha + y_{\phi} (l_\mu l_\tau + l_e \phi_2 l_\tau + l_e l_\mu \phi_3) \right] \frac{h h}{\Lambda} + h.c.
\]

Note that, in order for \( a, b \) and \( c \) to have the same phase, the three vevs \( \langle \phi_i \rangle \) should be real, that is the case as long as the flavon potential does not break CP. The other requirement is to keep \( M_e \) diagonal, with three different eigenvalues. This is promptly obtained as soon as the charged
Figure 5: The effective mass $m_{ee}$ as a function of $m_{light}$ for the neutrino mass matrix of Eq. (17), in the case of normal (left-hand panel) and inverse (right-hand panel) ordering. The solid line corresponds to the best fit input parameters $p_a$’s, while the purple shaded regions correspond to their $3\sigma$ allowed range. The green (blue) band is disfavoured by the cosmological upper bound on $\sum m_i$ (by $0\nu 2\beta$-decay searches).

lepton isosinglets $e_i^c$ also transform as an $A_4$-triplet. Introducing flavons $\varphi'$ and $\varphi''$ in the irreps $1'$ and $1''$ of $A_4$, respectively, one obtains

$$-\mathcal{L}_e = \left[ y_1 \sum_\alpha l_\alpha e^c_\alpha + y_1' \varphi'(l_e e^c + \omega l_\mu \mu^c + \omega^2 l_\tau \tau^c) \
y_1'' \varphi''(l_e e^c + \omega^2 l_\mu \mu^c + \omega l_\tau \tau^c) \right] h^* + h.c.,$$

where $\omega = \exp(2\pi i/3)$. This leads to $M_e = \text{diag}(m_e, m_\mu, m_\tau)$ as desired. Note that $A_4$ is broken to nothing in the neutrino sector, because one needs $\langle \phi_1 \rangle \neq \langle \phi_2 \rangle \neq \langle \phi_3 \rangle \neq 0$, while in the charged lepton sector a $Z_2 \times Z_2$ subgroup is preserved.

5 Minimal 1+2 lepton flavour symmetry

In the sections 3 and 4 we started from predictive mass matrix structures and built a flavour model to justify them. Here we follow the opposite path: we will construct a flavour model, with the minimal possible number of technical ingredients, and study the corresponding correlations between the observables.

Let us hypothesize that the three families of lepton doublets $l_i$ as well as the three charged lepton singlets $e_i^c$ transform in a dim-one and a dim-two irreps of a flavour symmetry group:

$$l_i \sim (1_l + 2_l)_i, \quad e_i^c \sim (1_{e^c} + 2_{e^c})_i.$$

In order to generate a non-zero mixing between the flavour singlet family and the doublet ones, it is mandatory to introduce a flavon in a dim-two irrep, $\phi \sim 2_0$, that acquires a non-zero vev. In the search for a minimal theory of lepton flavour, it is meaningful to ask whether a viable model
exists, that contains only flavons of this type, and what are the associated predictions.

The possible contributions to the lepton mass matrices are given by the irrep tensor products that are invariant under the flavour group:

\[
M_\nu \sim \begin{pmatrix}
(1_l \times 1_l)_1 & \ldots & (1_l \times 2_l \times 2_\nu^c)_1 \\
\vdots & \ddots & \vdots \\
(2_l \times 2_l)_1 & \ldots & (2_l \times 2_l \times 2_\nu^c)_1
\end{pmatrix},
\]

\[
M_e \sim \begin{pmatrix}
(1_l \times 1_{e^c})_1 & \ldots & (1_l \times 2_{e^c} \times 2_\nu^c)_1 \\
(2_l \times 1_{e^c} \times 2_\nu^c)_1 & \ldots & (2_l \times 2_{e^c} \times 2_\nu^c)_1
\end{pmatrix},
\]

where the subscript 1 denotes the invariant component in the tensor products, if any. Note that we included at most one power of the flavon irrep; this is the whole story if the theory is renormalizable and the flavon fields carry also gauge indexes, that is to say, \(\phi^c\) is a Higgs triplet, and \(\phi^c\) a Higgs doublet. Alternatively, one can treat the flavons as gauge singlets; in this case higher dimensional operators, suppressed by a cutoff scale \(\Lambda\), may contain several powers of the flavons, leading to more complicated flavour structures; here we will neglect these corrections of order \((\langle \phi \rangle / \Lambda)^n\).

Let us identify the simplest viable mass matrices with the structure given in Eq. (24) and Eq. (25). The minimal possibility is to employ a unique dim-two irrep \((2_l \equiv 2_{e^c} \equiv 2_\phi \equiv 2)\), and to assume that the tensor product \(2 \times 2\) contains a singlet, while \(2 \times 2 \times 2\) does not (to avoid an additional, unnecessary invariant). This is the case for the two non-abelian order-eight groups \(D_4\) and \(Q \equiv D'_2\), that satisfy \(2 \times 2 = \sum_{i=1}^4 1_i\), where \(1_i\) is the invariant singlet (we use conventions as in Ref. [18]). In the case of the quaternion group \(Q\), the invariant component in \(2_l \times 2_l\) is antisymmetric, therefore the corresponding contribution to \(M_\nu\) vanishes; we will see that such contribution is needed to accommodate the data, thus we will rather focus on the dihedral symmetry \(D_4\). In this case \((2_l \times 2_l)_1 = l_1 l_1 + l_2 l_2\) and the lepton mass matrices take the form

\[
M_\nu = \begin{pmatrix}
a & b & b' \\
\ldots & c & 0 \\
\ldots & \ldots & c
\end{pmatrix}, \quad M_e = \begin{pmatrix}
0 & B & B' \\
D & C & 0 \\
D' & 0 & C
\end{pmatrix},
\]

where the diagonal entries are independent from the flavons, while the off-diagonal ones are linear in the flavons. According to our minimality tenet, we put to zero the 11-entry of \(M_e\) by choosing \(1_l \times 1_{e^c} \neq 1_l\). Denoting the flavon vevs by \(\langle \phi^c \rangle = (\phi^c_u, \phi^c_d)_T\) and \(\langle \phi^c \rangle = (\phi^c_e, \phi^c_d^c)_T\), one has \(b/b' = \pm (\phi^c_u/\phi^c_d)^{\pm 1}\), \(B/B' = \pm (\phi^c_u/\phi^c_d)^{\pm 1}\) and \(D/D' = \pm (\phi^c_e/\phi^c_d^c)^{\pm 1}\), where the signs are not correlated and depend on the choice of the irreps \(1_l\) and \(1_{e^c}\).

The physical mixing matrix \(U_{PMNS}\) is determined as usual,

\[
M_\nu = U^\dagger_\nu d_\nu U_\nu^T, \quad M_e M_e^\dagger = U^\dagger_e d_e^2 U_e^T, \quad U_{PMNS} = U_e^T U_\nu,
\]

where \(d_\nu\) and \(d_e\) are diagonal matrices containing the neutrino and charged lepton mass eigenvalues. Let us remark that the vev of a doublet \(\phi\) breaks
$D_4$ completely, unless it is aligned in the directions $(1, \pm 1), (1, 0)$ or $(0, 1)$: in these cases a $Z_2$ subgroup is preserved. We will consider only these vev alignments, that are protected by the residual symmetry and correspond to a minimal number of parameters in the mass matrices. In the case $b = 0$ (or $b' = 0$), $M_\nu$ is diagonalized by a single rotation of angle $\theta_\nu$; the case $b = \pm b'$ can be reduced to the previous one by a $\pi/4$ rotation in the flavour doublet sector. Similarly, for $B = D = 0$ (or $B = D' = 0$, etc.), $M_e M_e^\dagger$ is diagonalized by a unique rotation $\theta_e$, while for $B = \pm B'$ and $D = \pm D'$ an additional maximal rotation is needed. If this maximal mixing is present (or absent) in both $M_\nu$ and $M_e M_e^\dagger$, it cancels out in $U_{\text{PMNS}}$ and it is straightforward to check that one entry of $U_{\text{PMNS}}$ vanishes, at odds with experimental data [3]. Thus, data indicate that $\phi''$ and $\phi^c$ should be two different flavons, one acquiring a vev in the direction $(1,0)$ or $(0,1)$, and the other in the direction $(1, \pm 1)$.

The general idea to break a flavour symmetry group $G$ to two different subgroups $G_\nu$ and $G_e$ in the neutrino and in the charged lepton sector, respectively, is not new: it was mostly employed to explain the tri-bi-maximal mixing pattern, in models where the three lepton doublets transform in a triplet representation of $G$ [19]. Here we have shown that, in the context of $1 + 2$ flavour models, the minimal viable possibility is to take $G_\nu = Z_2$ and $G_e = Z'_2$.

Let us derive the predictions of this scenario. Following the above considerations, in Eq. (26) we take $b' = 0$, $B' = B$ and $D' = -D$ (there are a few other equivalent assignments). Then, one can check that $M_\nu$ and $M_e M_e^\dagger$ depend on 6 independent absolute values of the matrix entries, plus 2 physical phases, therefore the 6 lepton masses, the 3 mixing angles and the 3 CP-violating phases are correlated, as we now describe. One finds

$$U_\nu = \begin{pmatrix}
\cos \theta_\nu e^{-i\alpha} & 0 & \sin \theta_\nu e^{-i\alpha} \\
-\sin \theta_\nu e^{i\alpha} & 0 & \cos \theta_\nu e^{i\alpha} \\
0 & 1 & 0
\end{pmatrix}, \quad d_\nu = \text{diag}(m_-, c, m_+), \quad (28)$$

where $\alpha = \text{arg}(ab^* + bc^*)/2$, $\tan 2\theta_\nu = 2|ab^* + bc^*|/(|c|^2 - |a|^2)$, $|m_\pm|^2 = |b|^2 + |a|^2/2 + |c|^2/2 \pm \sqrt{(|c|^2 - |a|^2)^2/4 + |ab^* + bc^*|^2}$. Note that the two independent mass squared differences $\Delta m^2_{ij}$ can be accommodated independently from the value of two parameters $\alpha$ and $\theta_\nu$, that enter in $U_{\text{PMNS}}$. In the charged lepton sector one has

$$U_e = \begin{pmatrix}
\cos \theta_e & \sin \theta_e e^{-i\beta} & 0 \\
\sin \theta_e e^{i\beta} & \cos \theta_e & 0 \\
\sqrt{2} & \sqrt{2} & \sqrt{2}
\end{pmatrix}, \quad d_e = \text{diag}(0, m_\mu, m_\tau), \quad (29)$$

with $\beta = \text{arg}(BC^*)$, $m_\mu^2 = 2|B|^2 + |C|^2$, $m_\tau^2 = 2|D|^2 + |C|^2$ and $\tan \theta_e = \sqrt{2}B/C$. Note that $m_e$ vanishes, which is a very good approximation, and
the two masses \(m_\mu\) and \(m_\tau\) are independent from the two parameters \(\theta_e\) and \(\beta\), that enter in \(U_{PMNS}\) (if the assignment of \(m_\mu\) and \(m_\tau\) were interchanged, \(\theta_e\) would be forced to lie close to \(\pi/2\) and the observed mixing angles could not be reproduced).

By using Eq. (27), one can easily check that \(\theta_{12}, \theta_{13}, \theta_{23}\) and \(\delta\) are a function of \(\theta_\nu\), \(\theta_e\) and a unique combination of phases, 2\(\alpha - \beta\), while the two physical Majorana-type phases are a function of the other independent combination of phases too. The correlation between the mixing angles and \(\delta\) depends on the assignment of the neutrino masses: we discuss first the case \(m_1 = |m_-|, m_2 = |c|\) and \(m_3 = |m_+|\), that corresponds to normal mass ordering. Comparing the predicted form of \(U_{PMNS}\) with its usual parameterization, we obtain

\[
2s_{12}^2c_{23}s_{13}^2 + 4s_{12}c_{12}s_{23}c_{23}s_{13}\cos\delta + 2c_{12}^2s_{23}^2 = 1. \tag{30}
\]

This relation is illustrated in Fig. 6. For the best fit values for \(\theta_{12}\) and \(\theta_{13}\), one finds \(\cos\delta \gtrsim 0.49\), and for \(\delta = 0\) one reaches the minimal value \(\sin^2\theta_{23} \simeq 0.616\), on the edge of the 1\(\sigma\) preferred region in the second octant.

Adding also \(\Delta m_{21}^2\) and \(\Delta m_{31}^2\) as input parameters, one can determine the lightest neutrino mass \(m_1\) and the 0\(\nu\)2\(\beta\)-decay effective mass \(m_{ee}\) as a function of \(\delta\) (or equivalently \(\theta_{23}\)) and of the extra phase \(\alpha\). This is because, in this scenario, in the basis where \(M_\nu\) is diagonal \(M_\nu\) depends on six parameters, therefore, after the four \(p_a\)'s are fixed, one can still vary two independent CP-violating phases. One can derive the explicit dependence of \(m_1\) and \(m_{ee}\) on \(\alpha\), by generalizing our procedure of section 2. For simplicity we limit ourselves to the CP-conserving case, because Eq. (30) favours a value of \(\delta\) close to zero, and because the value of \(m_{ee}\) for a CP-violating value of \(\alpha\) is intermediate between its two values in the CP-conserving case.
for $\delta = 0$ we obtain $m_1 \simeq 0.036$ eV and, for $\alpha = 0$ ($\alpha = \pi/2$), $m_{ee} \simeq 0.012$ eV ($m_{ee} \simeq 0.034$ eV).

We remark that Eq. (30) follows from our minimality assumptions, that is to say, it is the consequence of the simplest realization of a 1+2 flavour symmetry. This implies a non-maximal value of $\theta_{23}$ in the second octant. It is interesting to compare Eq. (30) with the relations among the mixing angles $\theta_{ij}$’s and the phase $\delta$, that have been obtained in Ref. [6]. In that approach one assumes that the flavour symmetry group is generated by a $Z_2$ symmetry in the neutrino sector plus a $Z_m$ symmetry in the charged lepton sector, with $m \geq 3$, and this leads to two constraints on the values of $\theta_{ij}$’s and $\delta$. The same analysis can be carried on in the present case, with $m = 2$, and we find that one of the two constraints is trivially satisfied, while the other is given by Eq. (30).

If the assignment of the neutrino mass eigenvalues is $m_1 = |m_-|$, $m_2 = |m_+|$ and $m_3 = |c|$, both normal and inverse orderings are possible, and Eq. (30) is replaced by

$$2c^2_{13}\epsilon^2_{23} = 1 .$$  \hspace{1cm} (31)

In this case the best fit value of $\theta_{13}$ corresponds to an almost maximal $2-3$ mixing, with $\sin^2 \theta_{23} \simeq 0.49$, a value (slightly) disfavoured by present data. The other assignments of the three neutrino mass eigenvalues are not viable.

## 6 Conclusions

We attempted to provide a modern view on the lepton mixing, and to propose some keys to interpret it. The underlying flavour dynamics may be intricate and difficult to disentangle, especially if it occurs at very large energy scales. Nonetheless, the effective structure of the lepton mass matrices may well be simple and depend on a small number of parameters. As a matter of fact, this must be the case for a flavour model to be testable.

Thus, it is useful to identify the minimal lepton mass matrices $M_\nu$ and $M_e$ compatible with those observables that have been measured precisely: the charged lepton masses, the mixing angles $\theta_{12}$ and $\theta_{13}$, and the neutrino mass squared differences $\Delta m^2_{ij}$. Such viable flavour structures imply definite predictions for the neutrino mass observables that are not precisely measured yet: the mixing angle $\theta_{23}$, the CP-violating phase $\delta$, the lightest neutrino mass $m_{\text{light}}$ and the $0\nu2\beta$-decay effective mass $m_{ee}$. We proposed a general procedure to illustrate the correlations between these observables.

In particular, it is intriguing that several minimal flavour structures imply a deviation from maximal $2-3$ mixing of the size that is presently suggested by the data. We identified a few classes of mass matrices with this property:

- A matrix $M_\nu$ with two zero entries and two other entries equal to each other, in the basis where $M_e$ is diagonal. There are two remarkable
The interval for $\sin^2 \theta_{23}$ displayed here is the 3$\sigma$ allowed range from a global fit of oscillation experiments [3]. The lowest, blue dots (bands) are the central values (the 1$\sigma$ ranges) in the two octants. The upper, red dots (bands) are the predictions of our models, assuming the central values (the 3$\sigma$ ranges) for the four parameters in Eq. (1). The three predictions correspond to Eq. (7) ($Q_6$ model), Eq. (14) ($A_4$ model), and Eq. (30) with $\delta = 0$ ($D_4$ model with no CP violation).

Figure 7: The interval for $\sin^2 \theta_{23}$ displayed here is the 3$\sigma$ allowed range from a global fit of oscillation experiments [3]. The lowest, blue dots (bands) are the central values (the 1$\sigma$ ranges) in the two octants. The upper, red dots (bands) are the predictions of our models, assuming the central values (the 3$\sigma$ ranges) for the four parameters in Eq. (1). The three predictions correspond to Eq. (7) ($Q_6$ model), Eq. (14) ($A_4$ model), and Eq. (30) with $\delta = 0$ ($D_4$ model with no CP violation).

17 cases: [i] $M_{\mu\mu} = M_{\tau\tau} = 0$ and $M_{e\mu(e\tau)} = M_{\mu\tau}$ or $M_{e\mu(e\tau)} = M_{ee}$ (section 2); [ii] $M_{ee} = M_{e\mu(e\tau)} = 0$ and $M_{\mu\tau} = M_{\mu\mu(\tau\tau)}$ (appendix).

We pointed out the properties of the flavour symmetry group that is needed to explain these matrix structures (section 3).

- An off-diagonal contribution to $M_\nu$ plus a contribution proportional to the identity, in the basis where $M_e$ is diagonal. Such structure is tailor-made for an $A_4$ flavour symmetry (section 4).

- Matrices $M_\nu$ and $M_e$ that respect each a different $Z_2$ symmetry, in such a way that only one free mixing angle is present in each sector. The minimal realization is provided by a $D_4$ symmetry, with the three lepton families transforming in the $1 + 2$ irreducible representations (section 5).

The three specific models that we presented predict $\theta_{23}$ close to its best fit values, as summarized in Fig. 7. Thus, the future precision measurements of this mixing angle will be able to confirm or rule out these scenarios. In order to discriminate among them, one shall use the correlated predictions for the mass ordering as well as for $\delta$, $m_{\text{light}}$ and $m_{ee}$, that could be all precisely measured within the next decade.

Appendix

Here we detail the procedure to derive the functions $x_i(x_j, p_a)$, defined in section 2, for a special class of Majorana neutrino mass matrices $M_\nu$ that depend on five physical parameters: the $3 \times 3$ symmetric matrices with two independent entries equal to zero. There are 15 such matrix structures, and only 7 of them are compatible with oscillation data, as first shown in Ref. [20] (see Ref. [21] for a recent analysis).

The four constraints relating the observables (3 neutrino mass eigenvalues, 3 mixing angles and 3 phases) have the form

$$0 = M_{\alpha\beta} = \sum_i (U_{PMNS}^*)_{\alpha i} (U_{PMNS}^*)_{\beta i} m_i,$$

for two independent complex entries $M_{\alpha_1\beta_1}$ and $M_{\alpha_2\beta_2}$. Since these equations are linear in $m_i$, they can be rewritten in the form

$$\frac{m_1}{m_3} e^{i\varphi_{13}} = f_{13}^*(\theta_{ij}, \delta), \quad \frac{m_2}{m_3} e^{i\varphi_{23}} = f_{23}^*(\theta_{ij}, \delta),$$

where $\varphi_{ij}$ are the Majorana phases and the functions $f_{ij}$ depend on the choice of $(\alpha_1, \beta_1)$ and $(\alpha_2, \beta_2)$,

$$f_{13} = \frac{U_{\alpha_1} U_{\beta_1}^* U_{\alpha_2} U_{\beta_2} - U_{\alpha_3} U_{\beta_3}^* U_{\alpha_2} U_{\beta_2}}{U_{\alpha_1} U_{\beta_1} U_{\alpha_2} U_{\beta_2} - U_{\alpha_1} U_{\beta_1} U_{\alpha_2} U_{\beta_2}^*},$$

$$f_{23} = \frac{U_{\alpha_1} U_{\beta_1} U_{\alpha_2} U_{\beta_2} - U_{\alpha_1} U_{\beta_1} U_{\alpha_2} U_{\beta_2}^*}{U_{\alpha_1} U_{\beta_1} U_{\alpha_2} U_{\beta_2} - U_{\alpha_1} U_{\beta_1} U_{\alpha_2} U_{\beta_2}^*},$$

where $U_{\alpha i}$ are the $U_{PMNS}$ entries without the Majorana phases. The neutrino mass squared differences can be expressed in terms of the neutrino masses as

$$\begin{cases} \Delta m_{21}^2 = m_3^2 (|f_{23}|^2 - |f_{13}|^2), \\ \Delta m_{31}^2 = m_3^2 (1 - |f_{13}|^2). \end{cases}$$

These equations are linear in $m_3^2$ and linear or quadratic in $\cos \delta$. Therefore the system has at most 2 solutions (for each given ordering of the mass spectrum) of the form

$$m_3^2 = m_3^2(\theta_{23}, p_a), \quad \cos \delta = \cos \delta(\theta_{23}, p_a),$$

18
where the input parameters $p_a$’s are defined in Eq. (1). Each solution is physical only when it fulfills the requirements $m_3^2 > 0$ and $|\cos \delta| \leq 1$. The effective $0\nu2\beta$-decay mass parameter can be written as

$$m_{ee} = m_3 \left| U_{e1}^* U_{e3}^* f_{13} + U_{e2}^* U_{e3}^* f_{23} + U_{e3}^* U_{e3}^* f_{33} \right| = m_{ee}(\theta_{23}, p_a),$$

where one has inserted the expressions for $m_3$ and $\delta$ given by Eq. (37). Analogously, any matrix element $M_{\alpha\beta}$ can be calculated as a function of $\theta_{23}$ and the $p_a$’s. The functions $x_i(\theta_{23}, p_a)$ for the observables $x_i = m_3, \delta, m_{ee}$ provide a parametric representation for the functions $x_i(x_j, p_a)$, for any pair $i, j$. This concludes the analytic computation of the observables for any $M_{\nu}$ with two zero entries.

The results for $M_{\mu\mu} = M_{\tau\tau} = 0$ (case C) were presented in section 2. Here we present the results for the 6 other viable cases:

$$A_1 : M_{\mu\mu} = M_{ee} = 0, \quad A_2 : M_{\mu\tau} = M_{ee} = 0, \quad (39)$$
$$B_1 : M_{e\tau} = M_{\mu\mu} = 0, \quad B_2 : M_{e\mu} = M_{\tau\tau} = 0, \quad (40)$$
$$B_3 : M_{e\mu} = M_{\mu\mu} = 0, \quad B_4 : M_{e\tau} = M_{\tau\tau} = 0. \quad (41)$$
The matrices in the second column are obtained from those in the first column, by the exchange of the 2nd and 3rd rows and columns, therefore their predictions are simply related by Eq. (4). Thus, we will illustrate the results for the cases $A_1$, $B_1$ and $B_3$ only, that for normal mass ordering correspond to $\theta_{23}$ in the first octant, as preferred by global fits [2, 3]. When inferring the results for the ‘specular’ cases, one should recall that the allowed experimental range for $\theta_{23}$ is slightly asymmetric between the first and the second octant.

For simplicity we fix the input parameters $p_a$’s to their best fit values: the predictions are slightly different when the small uncertainties on these parameters are taken into account. We present the plots for $m_{\text{light}}(\sin^2 \theta_{23}, p_a)$, $\delta(\sin^2 \theta_{23}, p_a)$ and $m_{\alpha\beta}(\sin^2 \theta_{23}, p_a)$, that are sufficient to infer the correlation between any pair of observables $x_i$’s.

• The results for the case $A_1$ are illustrated in Fig. 8.
  – Only a normal ordering of the neutrino mass spectrum is allowed.
  – The $2 - 3$ mixing satisfies $\sin^2 \theta_{23} < 0.505$, however this upper bounds relaxes substantially when allowing the $p_a$’s to vary in their $3\sigma$ allowed range.
  – The phase $\delta$ satisfies $\cos \delta < 0.62$.
  – The lightest mass $m_1$ lies in the range $[3.1, 6.3] \times 10^{-3}$ eV.
  – There is no contribution to the $0\nu2\beta$-decay rate.
  – In the $1\sigma$ preferred region for $\theta_{23}$, the equality $m_{\mu\mu} = m_{\mu\tau}$ can be realized. Therefore, as in the case $C$ discussed in section 2, the vanishing of two matrix entries and the equality of two others imply the desired prediction for $\theta_{23}$. One could build a model on the lines of the one in section 3 in order to justify this matrix structure by a discrete family symmetry.

• The results for the case $B_1$ are illustrated in Fig. 9.
  – Both normal and inverse ordering are allowed.
  – The angle $\theta_{23}$ lies in the first (second) in the case of normal (inverse) ordering. This statement remains valid when allowing the $p_a$’s to vary in their $3\sigma$ allowed range.
  – The phase $\delta$ is very close to $\pi/2$ (maximal CP-violation), with $|\cos \delta| < 0.13$ (a similar bound holds when the $3\sigma$ uncertainties on the $p_a$’s are taken into account).
  – There is a lower bound on the lightest neutrino mass, $m_1 > 2.8 \times 10^{-2}$ eV for normal and $m_3 > 2.6 \times 10^{-2}$ eV for inverse ordering.
  – There is a lower bound on the $0\nu2\beta$-decay effective mass, $m_{ee} > 2.8 \times 10^{-2}$ eV for normal or $m_{ee} > 5.5 \times 10^{-2}$ eV for inverse ordering.
Figure 9: The same as in Fig. 8, but for the case $m_{\mu\mu} = m_{e\tau} = 0$. The left-hand (right-hand) plots correspond to normal (inverse) ordering. The green (blue) bands are excluded by the cosmological upper bound on $\sum m_i$ (the experimental upper bound on $m_{ee}$). In the bottom panels, the thin solid blue line corresponds to $m_{ee}$, the thin dashed blue line to $m_{e\mu}$, the thick dotted red line to $m_{\mu\tau}$ and the thick solid red line to $m_{\tau\tau}$.

- The results for the case $B_3$ are illustrated in Fig. 10. They are qualitatively the same as in the case $B_1$, with minor modifications of the predicted range for the $x_i$’s.

In summary, our procedure allows to illustrate clearly all the predictions that follow from the assumption of two zero entries in $M_\nu$. We confirm that 8 matrix structures of this type are already excluded by present data. The 7 allowed matrix structures, analyzed above, could be ruled out by future measurements of the observables $x_i$’s. No matrix with three zero entries is allowed, because there is no intersection between the predictions of the different matrices with two zero entries.
Figure 10: The same as in Figs. 8 and 9 but for the case $m_{\mu\mu} = m_{e\mu} = 0$. In the bottom panels, the thin solid blue line corresponds to $m_{ee}$, the thin dotted blue line to $m_{e\tau}$, the thick dotted red line to $m_{\mu\tau}$ and the thick solid red line to $m_{\tau\tau}$.
