The optical anisotropy of a CNT enables oriented CNTs to function as a polarization switch.

I. INTRODUCTION

A carbon nanotube (CNT)\(^2\) absorbs light whose linear polarization is parallel to the tube’s axis (E\(_\parallel\)), but not when the polarization is perpendicular to it (E\(_\perp\)). The optical anisotropy of a CNT enables oriented CNTs to function as an optical polarizer.\(^5,6\) Recently, it was theoretically predicted that the polarization dependence is reversed by charge doping\(^\pm\) a doped CNT transmits E\(_\parallel\) and absorbs E\(_\perp\) (see Fig. 1).

![FIG. 1. Optical anisotropy of oriented CNTs. Oriented and undoped (doped) CNTs pass E\(_\perp\) (E\(_\parallel\)) only. Thus, oriented CNTs function as a polarization switch.](image)

The absorption of E\(_\perp\) originates from the resonant excitation of collective oscillations of electrons (plasmon), which differs entirely from the excitation of individual electrons or excitons by E\(_\parallel\) in an undoped CNT.\(^6,7\) This theory of plasmon resonance accounts qualitatively for the anomalous absorption peaks observed experimentally in doped CNTs.\(^6,7\) However, because the theoretical conclusion was derived using the Drude model which only takes account of intra-band electronic transitions, the exact doping and chirality dependencies of the absorption spectrum remain unknown.

In this paper we elucidate these dependencies by investigating the competition between intra and inter-band transitions with the Kubo formula. On the basis of predicted doping and chirality dependencies, we conclude that doped CNTs absorb E\(_\perp\) over frequencies ranging from infrared to visible. This expands the application range of CNT polarizers and suggests the possibility that the polarization direction of transmitted light is changed by 90 degrees with doping rather than by spatial rotation.

This paper is organized as follows. In Sec. II we explain the optical selection rule of CNTs. By calculating the dynamical conductivity, we show that momentum conservation and pseudospin play very essential role in determining the possible transitions. In Sec. III we examine absorption spectra for armchair and zigzag CNTs, which are the main result of this paper. The effect of Coulomb interaction on the absorption spectra is studied in Sec. IV. Our discussion is provided in Sec. V. The calculation details which are necessary to reproduce the results of Secs. II and III are given in Appendix.

II. SELECTION RULE

A. Parallel Polarization

The electronic transition caused by E\(_\parallel\) is a direct transition without a change in momentum of a photo-excited electron.\(^2\) In the band-diagram of a (10,10) armchair CNT shown in Fig. 2(a), each of the band curves plotted as a function of the wavevector along the tube’s axis (k\(_\parallel\)) is an eigenstate of the momentum around it and specified by magnetic quantum number m.\(^11\) The two bands with linear dispersion that cross each other at E = 0 have vanishing m, while the other curve is degenerate (±|m|) corresponding to the clockwise and anticlockwise circumferential motions, and the magnitude |m| increases with the energy |E|. Because the same m value appears in the conduction and valence bands symmetrically with respect to E = 0, there are two possible cases of direct transition: transition between the valence and conduction bands (inter-band transition) or within either band (intra-band transition).

The doping dependence of the direct inter-band transition is roughly known from Fermi-Dirac statistics. When the doping level is low, e.g. E\(_F\) = 0 eV (undoped), the direct inter-band transitions denoted by M\(_{11}\) and M\(_{22}\) in
Fig. 2(a) are both allowed by the Pauli exclusion principle while when the doping level is high, e.g. $E_F = 1$ eV, $M_{11}$ is forbidden, although $M_{22}$ is still allowed. In Fig. 2(b), the calculated real part of the dynamical conductivity $\text{Re}(\sigma_i)$ shows that the $M_{11}$ peak disappears when $E_F = 1$ eV. Meanwhile, a Drude peak corresponding to the direct intra-band transition denoted by $D$ in Fig. 2(a) develops in the zero-frequency limit of $\text{Re}(\sigma_i)$. The peak intensity increases with doping because the density of states at $E_F$ increases with doping. The disappearance of the $M_{11}$ peak and enhancement of the Drude peak are evidence of high doping that is provided by the absorption spectra of $E_i$.

This selection rule is a consequence of momentum conservation being applied to a case where, at the surface of a CNT, the azimuthal component of $E_\perp$ is approximately written as a sine (or cosine) function of the azimuthal angle ($\theta$) of the cylinder. More exactly, this is a consequence of momentum conservation being used in combination with the two facts that a plane wave is a superposition of different magnetic quantum numbers and that tube diameter $d_t$ of nanometer scale is much shorter than the light wavelength of micrometer scale. The proof goes as follows. When the light polarization is set perpendicular ($e_z$) to a tube’s axis ($e_z$), an incident plane wave of frequency $\omega$ and amplitude $E_{in}$ is written as $E_{in}e^{\pm i(ky-\omega t)}e_z$. In a cylindrical coordinate system $(r, \theta, z)$, the field is expressed as

$$E_\perp(r, \theta; t) = E_{in}e^{i(kr \sin \theta - \omega t)} \begin{pmatrix} \cos \theta \\ -\sin \theta \\ 0 \end{pmatrix}.$$  

By using the formula for the Bessel functions, $e^{ikr \sin \theta} = \sum_{m=-\infty}^{\infty} J_m(kr)e^{im\theta}$, we obtain the azimuthal component as

$$E_\theta = \sum_m \frac{E_{in}}{2j} (J_{m+1}(kr) - J_{m-1}(kr)) e^{im\theta - \omega t}. \quad (2)$$

Because $J_n(kr) \propto (kr)^n$, $|E_\theta|$ is dominated by the modes with $m = \pm 1$ when $kr \ll 1$, which we assume throughout this paper. By applying the momentum selection rule to the band-diagram in Fig. 2(c) we can expect that the transitions denoted by $A$ and $B$ to develop the peaks in $\text{Re}(\sigma_\perp)$ for an undoped and doped CNT, respectively, and these are confirmed in Fig. 2(d).

The selection rule, $\Delta m = \pm 1$, explained above is a result of the momentum conservation only, and the indirect transitions are further restricted to the forward scattering by the symmetry that originates from the two sublattices nature of the electronic wavefunction known as pseudospin. For example, it suppresses a transition (of the backward scattering) denoted by $C$ in Fig. 2(c) to develop a strong peak in $\text{Re}(\sigma_\perp)$ like the $M_{11}$ and $M_{22}$ peaks although it is a transition between band-edges with a large density of states. A profound effect of pseudospin on the selection rule is more clearly seen for a doped semiconducting CNT. In the band-diagram of a (16,0) zigzag CNT shown in Fig. 2(a), each of the band curves is specified by shifted magnetic quantum number $m = \pm m_0 + n$ where $m_0$ is a nonzero integer ($m_0 = 11$) and $n = 0, \pm 1, \cdots$. When $E_F = 0.4$ eV, the transition denoted by $C$ with $\Delta m = 1$ is allowed by the momentum selection rule, however, it is actually forbidden by pseudospin. Meanwhile the transition denoted by $B$ with $\Delta m = -1$ is fully allowed. This difference is peculiar because the transition energy of $C$ is smaller than that of $B$. It becomes clear that $B$ ($C$) is forward (backward) scattering by drawing the three-dimensional band-diagram in the inset of Fig. 2(b). As a result of pseudospin the peak position in $\text{Re}(\sigma_\perp)$ is approximately given by 0.8 eV. The

### FIG. 2. Selection rule of armchair CNTs.

(a) The direct transitions caused by $E_i$ ($\Delta m = 0$) are denoted by arrows. (b) Calculated real part of the dynamical conductivity along $E_i$, $\text{Re}(\sigma_i)$, is shown for different Fermi energy positions. The vertical axis is given in units of $e^2/h$, where $e$ is electron charge magnitude and $h$ Planck constant. (c) The momentum selection rule of $E_\perp$ is $\Delta m = \pm 1$. The inter-band transitions with $m = 0 \rightarrow \pm 1$ are denoted by $A$ and these are allowed (forbidden) for low (high) doping. When $E_F = 1$ eV, the intra-band transitions with $m = +1 \rightarrow +2$ or $-1 \rightarrow -2$ are allowed and these are denoted by $B$. The transition $C$ is suppressed by pseudospin. (d) $\text{Re}(\sigma_\perp)$ is shown for different Fermi energy positions.

### B. Perpendicular Polarization

The electronic transition caused by $E_\perp$ is the indirect transition, and transitions with an $m$ change of $\pm 1$, $\Delta m = \pm 1$, are dominant over transitions with $|\Delta m| \geq 2$. The
peak position of the doped zigzag CNT is similar to that of the doped armchair CNT (B in Fig. 2(d)) regardless of the difference of the band-diagrams of the zigzag and armchair CNTs. It should be noted that the lack of the transition C with \( \Delta m = 1 \) does not mean that there is an asymmetry between the clockwise and anticlockwise circumferential motions of the electrons. Each band with the index \( n \) is actually degenerate (\( \pm m_0 \)) corresponding to the different valleys, and the subband with \( n \) in one valley relates with the subband with \( -n \) in the other valley. Thus the lack of the transitions with \( \Delta m = 1 \) in one valley means the transitions with \( \Delta m = 1 \) in different valley are allowed.

![Diagram of Selection rule of zigzag CNTs](image)

**FIG. 3. Selection rule of zigzag CNTs.** (a) The inter-band transitions denoted by \( A \) and \( A' \) are allowed when \( E_F = 0 \) eV. Because \( A \) and \( A' \) are the forward scattering, a single peak develops in Re(\( \sigma_\perp \)) as shown in (b). When \( E_F = 0.4 \) eV, the peak intensity halves because \( A' \) is not allowed by exclusion principle whereas \( A \) is still allowed. Besides, the intra-band transition \( B \) is allowed by pseudospin. The three dimensional band-diagram shows that the transitions \( A, A', \) and \( B \) are all the forward scattering, while \( C \) is the backward scattering that is forbidden by pseudospin.

### III. DEPOLARIZATION AND PLASMON

According to the selection rule only, we may expect the peaks caused by \( \mathbf{E}_\perp \), such as \( A \) in Fig. 2(d) and \( A + A' \) in Fig. 3(b), to appear in the absorption spectra of undoped CNTs. However, it is not. The calculated absorption spectrum which is given by the real part of the dynamical conductivity divided by the relative permittivity \( \varepsilon_\perp \), Re(\( \sigma_\perp / \varepsilon_\perp \)) does not exhibit the corresponding peak when \( E_F = 0 \) eV, as shown in the inset of Fig. 4. This is widely known as the depolarization effect. As a result of the momentum transfer from \( \mathbf{E}_\perp \) to an electron, a non-uniform density distribution around the tube’s axis similar to an electric dipole is introduced and induces a depolarization field. When the doping level is low, the depolarization field almost cancels out the applied field, and the total field defined by the sum of the applied and depolarization fields, is suppressed. Even though the electronic transition is allowed by the selection rule, the electron does not undergo a transition since the electric field by itself almost disappears due to the depolarization effect.

**FIG. 4. Calculated absorption spectra for doped armchair and zigzag CNTs.** The absorption spectrum that includes the depolarization effect is given by the real part of the dynamical conductivity divided by the relative permittivity \( \varepsilon_\perp \), Re(\( \sigma_\perp / \varepsilon_\perp \)) (\( \equiv \) Re(\( \tilde{\sigma}_\perp \)). The peak originates from a resonant excitation of plasmon caused by doping. The inset shows the depolarization effect in undoped CNTs.

The main point of this paper is that the efficacy of the depolarization field depends strongly on doping. When the doping level is as high as \( E_F = 1 \) eV, absorption peaks develop in the region \( \hbar \omega = 1.2 \approx 1.3 \) eV as shown in Fig. 4. It can be shown that these peaks originate from the fact that the depolarization field is strongly enhanced at the specific frequency. Even if an infinitely small electric field is applied to a doped CNT, the depolarization field has a finite amplitude. This state is produced by the self-sustaining collective motion of the electrons (plasmon or plasmon-polariton), which is in sharp contrast to the single-particle excitation constituting the absorption peaks of \( \mathbf{E}_\parallel \). Meanwhile, the Drude peak is absent for \( \mathbf{E}_\parallel \), which is also in contrast to the case of \( \mathbf{E}_\perp \).

The total electric field that the electrons in a CNT really “see” is given by the applied field divided by the relative permittivity \( \varepsilon_\perp / \varepsilon_\parallel \). Mathematically, it is shown that by solving Maxwell equations while taking account of the boundary conditions at the tube’s surface, \( \varepsilon_\perp \) is written as

\[
\varepsilon_\perp = 1 - \frac{\sigma_\perp(E_F)}{i\omega d_i \varepsilon_\perp},
\]

where \( d_i \) is the diameter of a CNT and \( \varepsilon_\parallel \) is the permittivity of the surrounding medium. To observe that the vanishing real part of \( \varepsilon_\perp \) is essential for the appearance of plasmon, we plot the real and imaginary parts of \( \varepsilon_\perp \) as a function of energy in Fig. 5(a) for undoped and doped CNTs. Indeed, when \( E_F = 1 \) eV, Re(\( \varepsilon_\perp \)) vanishes at an energy that corresponds to the absorption peak position seen in Fig. 4.
helps the total electric field to enhance in a resonant fashion. Note that in the present calculations a surrounding medium with \( \epsilon = 2\epsilon_0 \) is assumed where \( \epsilon_0 \) is the permittivity of free space, and that a large value of \( \epsilon/\epsilon_0 \) has the advantage of decreasing the plasmon energy, because \( \text{Re}(\epsilon_\perp) \) shifts upward in effect and zero of which shows a redshift.

To understand the cause of the appearance of plasmons in the doped CNTs more clearly, we consider the relative significance of the contributions made by intra and inter-band transitions to \( \text{Re}(\epsilon_\perp) \). By noting that in Eq. (3) \( \text{Re}(\epsilon_\perp) \) is proportional to the imaginary part of the dynamical conductivity, \( \text{Im}(\sigma_\perp) \), we show each contribution, \( \text{Im}(\sigma_\perp^{\text{intra}}) \) and \( \text{Im}(\sigma_\perp^{\text{inter}}) \), for the representative case of high doping level \( (E_F = 1 \text{ eV}) \) in Fig. 5(b). \( \text{Im}(\sigma_\perp^{\text{inter}}) \) is a negative value for the frequency range of interest. Thus, if we neglect the intra-band transitions, \( \text{Re}(\epsilon_\perp) > 0 \) and the condition for plasmon existence is unsatisfied. When \( E_F = 1 \text{ eV} \), the contribution made by the intra-band transition \((B)\) causes a peak in \( \text{Im}(\sigma_\perp^{\text{intra}}) \) so that \( \text{Re}(\epsilon_\perp) \) exhibits a dip at \( \hbar \omega \approx 0.8 \text{ eV} \). With increasing \( \hbar \omega \) from a dip, \( \text{Im}(\sigma_\perp^{\text{intra}}) \) decreases and \( -\text{Im}(\sigma_\perp^{\text{inter}}) \) increases. As a result, \( \text{Re}(\epsilon_\perp) \) becomes zero at around 1.2 eV and the sign of \( \text{Re}(\epsilon_\perp) \) changes at the energy. It is interesting that when combined with the intra-band transitions, the contribution of the inter-band transitions to the dynamical conductivity is not negligible since it tends to redshift the plasmon energy when \( E_F = 1 \text{ eV} \).

Figure 6 shows the details of the \( E_F \) dependence of the absorption spectra of a \((10,10)\) armchair \((d_t = 1.35 \text{ nm})\) and \((16,0)\) zigzag CNTs \((d_t = 1.25 \text{ nm})\). There are several noticeable features should be mentioned. Firstly, the plasmon peak starts to develop when the \( M_{11} (S_{22}) \) peak by \( E_\parallel \) starts to disappear for the armchair (zigzag) CNT. Secondly, the plasmon peak intensity and frequency increase as increasing \( E_F \). Thirdly, the doping dependence of the plasmon frequency in the armchair CNT is similar to that in the zigzag CNT. This suggests that when CNTs are intentionally doped, they will eventually have a similar excitation structure regardless of the chirality. Finally, the plasmon peak is present in the dispersion region (or the vicinity thereof) where single particle excitation is not allowed, indicating that a plasmon cannot collapse into individual electron-hole pairs and the kinematic stability is guaranteed for the plasmon.

To understand the cause of the appearance of plasmons in the doped CNTs more clearly, we consider the relative significance of the contributions made by intra and inter-band transitions to \( \text{Re}(\epsilon_\perp) \). By noting that in Eq. (3) \( \text{Re}(\epsilon_\perp) \) is proportional to the imaginary part of the dynamical conductivity, \( \text{Im}(\sigma_\perp) \), we show each contribution, \( \text{Im}(\sigma_\perp^{\text{intra}}) \) and \( \text{Im}(\sigma_\perp^{\text{inter}}) \), for the representative case of high doping level \( (E_F = 1 \text{ eV}) \) in Fig. 5(b). \( \text{Im}(\sigma_\perp^{\text{inter}}) \) is a negative value for the frequency range of interest. Thus, if we neglect the intra-band transitions, \( \text{Re}(\epsilon_\perp) > 0 \) and the condition for plasmon existence is unsatisfied. When \( E_F = 1 \text{ eV} \), the contribution made by the intra-band transition \((B)\) causes a peak in \( \text{Im}(\sigma_\perp^{\text{intra}}) \) so that \( \text{Re}(\epsilon_\perp) \) exhibits a dip at \( \hbar \omega \approx 0.8 \text{ eV} \). With increasing \( \hbar \omega \) from a dip, \( \text{Im}(\sigma_\perp^{\text{intra}}) \) decreases and \( -\text{Im}(\sigma_\perp^{\text{inter}}) \) increases. As a result, \( \text{Re}(\epsilon_\perp) \) becomes zero at around 1.2 eV and the sign of \( \text{Re}(\epsilon_\perp) \) changes at the energy. It is interesting that when combined with the intra-band transitions, the contribution of the inter-band transitions to the dynamical conductivity is not negligible since it tends to redshift the plasmon energy when \( E_F = 1 \text{ eV} \).

Figure 6 shows the details of the \( E_F \) dependence of the absorption spectra of a \((10,10)\) armchair \((d_t = 1.35 \text{ nm})\) and \((16,0)\) zigzag CNTs \((d_t = 1.25 \text{ nm})\). There are several noticeable features should be mentioned. Firstly, the plasmon peak starts to develop when the \( M_{11} (S_{22}) \) peak by \( E_\parallel \) starts to disappear for the armchair (zigzag) CNT. Secondly, the plasmon peak intensity and frequency increase as increasing \( E_F \). Thirdly, the doping dependence of the plasmon frequency in the armchair CNT is similar to that in the zigzag CNT. This suggests that when CNTs are intentionally doped, they will eventually have a similar excitation structure regardless of the chirality. Finally, the plasmon peak is present in the dispersion region (or the vicinity thereof) where single particle excitation is not allowed, indicating that a plasmon cannot collapse into individual electron-hole pairs and the kinematic stability is guaranteed for the plasmon.
In this section, we examine how the Coulomb interaction affects the results presented in the preceding sections. Because the Coulomb interaction weakens at high doping or in a metallic CNT due to the screening effect, we focus on a semiconducting CNT at low doping level. The results shown in this section are obtained by extending the existing framework developed for calculating exciton of an undoped CNT\textsuperscript{22,23} to a doped CNT. The details will be presented elsewhere.\textsuperscript{24}

The Coulomb interaction changes the absorption spectrum through two main effects: self-energy correction to the band-diagram (band renormalization) and formation of excitons. First we show the band renormalization.

### A. Band Renormalization

The thick curved lines in Fig. 7 show the renormalized band-diagram of a (16,0) zigzag CNT, which is given by adding the screened exchange energy (or self-energy) to the original (bare) band-diagram denoted by the thin curved lines. When $E_F = 0$ eV, the self-energy makes the band gap increase significantly. When $E_F = 0.5$ eV, on the other hand, the self-energy is modest; the band gap is almost identical to that of the bare band. This is due to that the electron-hole pairs within the conduction band screen more effectively the Coulomb interaction than the inter-band electron-hole pairs.\textsuperscript{21} Note also that the self-energy for the states away from the Fermi level does not vanish and this tends to blue-shift the plasmon peak.

![FIG. 7. Band renormalization of zigzag CNTs.](image)

The exciton formation together with the band renormalization changes the absorption spectrum significantly. When $E_F = 0$ eV, the absorption peaks of $E_{\parallel}$ are governed by excitons as shown in Fig. 8. By comparing the result with the spectrum calculated without the Coulomb interaction, the sizable enhancement of oscillator strength is seen for each peak. Meanwhile, the correction to the absorption spectrum of $E_{\perp}$ is minor: a small peak due to the exciton formation is observed in Re($\tilde{\sigma}_{\perp}$). These results are consistent with Refs. 22 and 23.

![FIG. 8. Absorption spectra calculated with and without Coulomb interaction.](image)

### B. Absorption Spectra

Figure 9(a) shows the behavior of the absorption peaks of $E_{\parallel}$ under doping. When $E_F = 0.5$ eV, the $S_{11}$ peak disappears due to exclusion principle. The peak intensity of $S_{22}$ ($S_{33}$) is suppressed by doping.\textsuperscript{2} Further increase of doping results in that the $S_{22}$ and $S_{33}$ peaks exhibit red-shift due to the band renormalization. The red-shift of the peaks serves as a unique information of the self-energy because the peak positions should not change when the self-energy correction is not taken into account (see Fig. 8). As shown in Fig. 9(b), the exciton peak of $E_{\perp}$ disappears soon after $E_F$ reaches the bottom of the first subband ($E_F = 0.5$ eV), and the plasmon peak develops when $E_F = 1$ eV. Such transition from exciton to plasmon may be observed when the broadening of the exciton of an undoped CNT is sufficiently suppressed.\textsuperscript{22}

### V. DISCUSSION

We compare the present results with experimental ones. Kazaoui et al. found a broad peak in the absorption by thin films of heavily doped single-walled CNTs.\textsuperscript{2} The pristine films consist of semiconducting and metallic CNTs since $S_{11}$ (0.68 eV), $S_{22}$ (1.2 eV), and $M_{11}$ (1.8 eV) are all observed. The doping-induced peak appears when $S_{11}$, $S_{22}$, and $M_{11}$ disappear by doping, which is consistent with our results. It was found that the peak energy depends on doping level: 1.07 eV (1.3 eV) for CB$_{0.15}$
able to orient CNTs that are doped and separated into a single chirality. In the past, the depolarization effect was experimentally verified by absorption and Raman spectroscopy in which undoped CNTs are oriented by stretching the organic films on which they are dispersed or by controlling magnetic effects or CNT growth processes. Although experiments have already been performed on the doping dependence of light absorption for CNTs with a single chirality, there is no corresponding absorption measurements for oriented and doped CNTs. Recently, He et al. developed a technology for aligning CNTs spontaneously by improving vacuum filtration and this approach can be used for the purpose.

If doped CNTs can be oriented, they will provide an opportunity for searching for novel phenomena even if they are not separated into a single chirality. Because the anisotropy of light absorption is related to the anisotropy of the electron-phonon interaction, there is a strong possibility that characteristic signals of doping will be explored by the polarized Raman spectroscopy. For example, in doped metallic CNTs, phonon frequency hardening have been observed in the manner that depends on the phonon eigenvector. A phenomenon similar to it should be observed also for semiconducting CNTs.

The idea of the polarization reversal of light absorption in doped CNTs can also be applied to doped graphene nanoribbons, because it has been shown that the optical selection rule of nanoribbons is similar to that of CNTs. However, a modification of Eq. (3) caused by the edge is needed for nanoribbons and the coupling of nanoribbons to the substrate must be taken into account.

Since the length of a CNT is finite in the axial direction, there is also a depolarization effect in the axial direction. The optical selection rule of finite length CNTs is obtained by extending the calculations on a nanoribbon. Indeed, due to the formation of a standing wave by the ends of a CNT, it can be proved that there is a wavelength shift of roughly the reciprocal of the axial length, which can explain why the plasmon peak is formed in the terahertz region of $E_p$.

Here, we mention a subject closely related to the optical properties of doped CNTs, that is, quantum wells. The band-diagram of a CNT bears a similarity to that of a quantum well and the concepts such as depolarization and exciton effects have been used to understand the optical properties of quantum wells. The term “intersubband transitions” is commonly used to describe only the transitions within the conduction band of quantum wells. This is a reasonable assumption when the width of doped quantum wells is approximately 10 nm or longer. For CNTs with diameter of the order of 1 nm, however, the inter-band transitions have very important effects on absorption spectrum for both undoped and doped cases. Note also that the pseudospin selection rule is a fundamental new point of CNTs, not seen in quantum wells.

Two degrees of freedom of the light polarization are utilized in modern optical transmission technology to double the amount of information transmitted simultane-

---

FIG. 9. Doping dependence of absorption spectra with Coulomb interaction. (a) When $E_F = 0.5$ eV, the $S_{11}$ peak is invisible due to the exclusion principle and the doping dependence of the $S_{22}$ peak exhibits a red-shift as indicated by the horizontal arrow. (b) The small exciton peak when $E_F = 0$ eV is replaced by plasmon peak when $E_F = 1$ eV. This transition may be observed when the exciton peak is observable. The arrow above the plasmon peak shows that the plasmon energy increases with increasing doping.
ously. For example, a light is propagated by associating its parallel polarization with pictorial information and perpendicular polarization with sound. Nano-scale materials that respond differently depending on polarization direction are advantageous for information manipulation in highly refined structures where light propagates, for example as an extremely thin Polaroid film. The fact that CNTs can be rotated by 90 degrees simply by doping implies the possibility of performing further information manipulation by electric means. From the viewpoint of condensed matter physics, the doping-induced change in the polarization direction of light transmitted through CNTs can be rotated by 90 degrees simply by doping and the surface area of a CNT (S) is $3a_{cc} \times 2\sqrt{3}a_{cc}L$. As a result of the longer axial length than the diameter ($L \gg n$), the band diagram of a CNT is well described by the cross sections of the Dirac cones (see Fig. 3(b)). We also note that the effect of orbital hybridization between $\pi$ and $\sigma$ due to the curvature of the azimuthal direction is negligible in this study.

We employed a tight-binding model with the hopping integral $\gamma = 2.6$ eV and atomic distance $a_{cc} = 1.42$ Å, to calculate the band diagram and wavefunction of the $\pi$ electrons in CNTs. As a function of wavevector $k = (k_x, k_y)$, the model Hamiltonian is written in the form of a $2 \times 2$ matrix:

$$H(k) = -\gamma \begin{pmatrix} 0 & f(k) \\ f(k)^* & 0 \end{pmatrix}. \tag{A1}$$

The off diagonal element $f(k)$ is a complex number given by

$$f(k) = e^{ik_ya_{cc}} + 2e^{-i\frac{ky_{acc}}{2}} \cos \left(\frac{\sqrt{3}k_xa_{cc}}{2}\right), \tag{A2}$$

and $f(k)^*$ denotes the complex conjugate of $f(k)$. By expressing the energy eigenvalue equation $H(k)|\phi_k^s\rangle = \epsilon_k^s|\phi_k^s\rangle$ in terms of the magnitude and phase of $f(k)$ as $f(k) = |f(k)|e^{-i\Theta(k)}$, we obtain the energy eigenvalue and Bloch wavefunction as $\epsilon_k^s = -s\gamma|f(k)|$ and

$$|\phi_k^s\rangle = \frac{1}{\sqrt{2}} \begin{pmatrix} e^{-i\Theta(k)} \\ s \end{pmatrix}, \tag{A3}$$

respectively. The band index $s = \pm 1$ ($s = -1$) corresponds to the valence (conduction) band. The low energy band diagram near the charge neutral point $\epsilon_k^s \sim 0$ is given by a pair of double cones (known as the Dirac cones).

Because the interaction between the electron and light $\delta H$ is given by the minimal substitution, $k_i \rightarrow k_i - \frac{1}{2\hbar}A_i$, the electric currents defined from $\delta H = J_iA_i$ are

$$J_i = -\frac{e}{\hbar} \frac{\partial H(k)}{\partial k_i} \quad (i = x, y). \tag{A4}$$

Putting Eqs. (A1) and (A2) into Eq. (A3) we have the following expressions of the current operators,

$$J_x = -ev \frac{2}{3} \sin \left(\frac{\sqrt{3}k_xa_{cc}}{2}\right) \begin{pmatrix} 0 & e^{-ik_ya_{cc}} \\ e^{ik_ya_{cc}} & 0 \end{pmatrix},$$

$$J_y = -ev \frac{2}{3} \begin{pmatrix} 0 & e^{-ik_ya_{cc}} - e^{ik_ya_{cc}} \cos \left(\frac{\sqrt{3}k_xa_{cc}}{2}\right) \\ i\left(e^{-ik_ya_{cc}} - e^{ik_ya_{cc}} \cos \left(\frac{\sqrt{3}k_xa_{cc}}{2}\right)\right) & 0 \end{pmatrix}, \tag{A5}$$

where $v = 3\gamma a_{cc}/2\hbar$ is the Fermi velocity of graphene.

The wavevectors are quantized by the periodic boundary condition around and along the tube’s axis. For the case of armchair $(n, n)$ CNTs, the quantized wavevectors are specified by two integers $m$ and $j$ as

$$k_y \frac{3a_{cc}}{2}n = m\pi, \quad (m = -n + 1, \ldots, n), \tag{A7}$$

$$k_x \frac{\sqrt{3}a_{cc}}{2}2L = j\pi, \quad (j = -L, \ldots, L). \tag{A8}$$

Note that $2\sqrt{3}a_{cc}L$ is the CNT length, $3a_{cc}n/\pi$ is the diameter, and the surface area of a CNT ($S$) is $3a_{cc}n \times 2\sqrt{3}a_{cc}L$. As a result of the longer axial length than the diameter ($L \gg n$), the band diagram of a CNT is well described by the cross sections of the Dirac cones (see Fig. 3(b)). We also note that the effect of orbital hybridization between $\pi$ and $\sigma$ due to the curvature of the azimuthal direction is negligible in this study.

Appendix A: Method

We employed a tight-binding model with the hopping integral $\gamma = 2.6$ eV and atomic distance $a_{cc} = 1.42$ Å, to calculate the band diagram and wavefunction of the $\pi$ electrons in CNTs. As a function of wavevector $k = (k_x, k_y)$, the model Hamiltonian is written in the form of a $2 \times 2$ matrix:

$$H(k) = -\gamma \begin{pmatrix} 0 & f(k) \\ f(k)^* & 0 \end{pmatrix}. \tag{A1}$$

The off diagonal element $f(k)$ is a complex number given by

$$f(k) = e^{ik_ya_{cc}} + 2e^{-i\frac{ky_{acc}}{2}} \cos \left(\frac{\sqrt{3}k_xa_{cc}}{2}\right), \tag{A2}$$

and $f(k)^*$ denotes the complex conjugate of $f(k)$. By expressing the energy eigenvalue equation $H(k)|\phi_k^s\rangle = \epsilon_k^s|\phi_k^s\rangle$ in terms of the magnitude and phase of $f(k)$ as $f(k) = |f(k)|e^{-i\Theta(k)}$, we obtain the energy eigenvalue and Bloch wavefunction as $\epsilon_k^s = -s\gamma|f(k)|$ and

$$|\phi_k^s\rangle = \frac{1}{\sqrt{2}} \begin{pmatrix} e^{-i\Theta(k)} \\ s \end{pmatrix}, \tag{A3}$$

respectively. The band index $s = \pm 1$ ($s = -1$) corresponds to the valence (conduction) band. The low energy band diagram near the charge neutral point $\epsilon_k^s \sim 0$ is given by a pair of double cones (known as the Dirac cones).

Because the interaction between the electron and light $\delta H$ is given by the minimal substitution, $k_i \rightarrow k_i - \frac{1}{2\hbar}A_i$, the electric currents defined from $\delta H = J_iA_i$ are

$$J_i = -\frac{e}{\hbar} \frac{\partial H(k)}{\partial k_i} \quad (i = x, y). \tag{A4}$$

Putting Eqs. (A1) and (A2) into Eq. (A3) we have the following expressions of the current operators,

$$J_x = -ev \frac{2}{3} \sin \left(\frac{\sqrt{3}k_xa_{cc}}{2}\right) \begin{pmatrix} 0 & e^{-ik_ya_{cc}} \\ e^{ik_ya_{cc}} & 0 \end{pmatrix},$$

$$J_y = -ev \frac{2}{3} \begin{pmatrix} 0 & e^{-ik_ya_{cc}} - e^{ik_ya_{cc}} \cos \left(\frac{\sqrt{3}k_xa_{cc}}{2}\right) \\ i\left(e^{-ik_ya_{cc}} - e^{ik_ya_{cc}} \cos \left(\frac{\sqrt{3}k_xa_{cc}}{2}\right)\right) & 0 \end{pmatrix}, \tag{A5}$$

where $v = 3\gamma a_{cc}/2\hbar$ is the Fermi velocity of graphene.

The wavevectors are quantized by the periodic boundary condition around and along the tube’s axis. For the case of armchair $(n, n)$ CNTs, the quantized wavevectors are specified by two integers $m$ and $j$ as

$$k_y \frac{3a_{cc}}{2}n = m\pi, \quad (m = -n + 1, \ldots, n), \tag{A7}$$

$$k_x \frac{\sqrt{3}a_{cc}}{2}2L = j\pi, \quad (j = -L, \ldots, L). \tag{A8}$$

Note that $2\sqrt{3}a_{cc}L$ is the CNT length, $3a_{cc}n/\pi$ is the diameter, and the surface area of a CNT ($S$) is $3a_{cc}n \times 2\sqrt{3}a_{cc}L$. As a result of the longer axial length than the diameter ($L \gg n$), the band diagram of a CNT is well described by the cross sections of the Dirac cones (see Fig. 3(b)). We also note that the effect of orbital hybridization between $\pi$ and $\sigma$ due to the curvature of the azimuthal direction is negligible in this study.

specified by two integers m and j as
\[ k_y \frac{3 a_{cc}}{2} 2L = j \pi, \quad (j = -L, \ldots, L), \quad (A9) \]
\[ k_z \frac{\sqrt{3 a_{cc}}}{2} n = m \pi, \quad (m = -n + 1, \ldots, n). \quad (A10) \]
Note that 6a_{cc}L is the CNT length, \( \sqrt{3 a_{cc}}n/\pi \) is the diameter, and the surface area of a CNT is the same as \((n, n)\) CNTs.

We calculated the dynamical conductivity in the framework of the linear response theory,
\[ \sigma_{\Delta m}(\omega, E_F) \equiv g_{\text{spin}} \frac{\hbar}{iS} \sum_{m', s, m, j} \left| f_{m+\Delta m, j}(E_F) - f_{m, j}(E_F) \right|^2 \left| \langle \phi_{m+\Delta m, j}^{s'} | J_l | \phi_{m, j}^{s} \rangle \right|^2, \quad (A11) \]
where \( g_{\text{spin}} = 2 \) is the spin degeneracy, \( f_k(E_F) = 1/(e^{\varepsilon_k/E_F} - 1) \) is the Fermi distribution function at room temperature \( (kT = 1/38.6 \text{ eV}) \), and \( \delta (= \hbar/\tau) \) is inversely proportional to the relaxation time of an excited electron. We fix \( \delta = 50 \text{ meV} \) \((\tau \approx 13 \text{ fs})\) in all calculations. For an armchair CNT, the current operator \( J_l (J_y) \) couples to \( E_{||} (E_{\perp}) \). Due to the momentum selection rule \( \Delta m = 0 \) for \( E_{\parallel} \), the absorption \( J_x E_x \) is the product of
\[ \sigma_0 \] \hspace{1cm} (A12)
and \( E_x^2 \), while for \( E_{\perp} \), the absorption \( J_y E_y \) is the product of
\[ \frac{1}{2} \left[ \frac{\sigma_{+1}}{1 - \varepsilon_{m, j}^{\parallel}} + \frac{\sigma_{-1}}{1 - \varepsilon_{m, j}^{\parallel}} \right] \] \hspace{1cm} (A13)
and \( E_y^2 \). The factor one-half in Eq. (A13) originates from the field decomposition of \( E_y \) into the pair \( \Delta m = \pm 1 \). Equations (A12) and (A13) are the exact definition of the absorption plotted in the text as \( \sigma_{\parallel} \) and \( \sigma_{\perp} \), respectively. Note also that \( \sigma_{+1} = \sigma_{-1} (\equiv \sigma_{\perp}) \) holds in the absence of the Aharonov-Bohm flux along the tubule axis.

It is instructive to evaluate the matrix element to show that only the forward scattering is allowed by the selection rule of pseudospin. We take zigzag CNTs and focus on the transitions between band edges \( (k_y = 0) \). The matrix element of \( J_x \) is known from Eqs. (A3) and (A5) as
\[ \langle \phi_{m'}^{s'} | J_x | \phi_{m}^{s} \rangle \propto 1 + ss' e^{i(\Theta' + \Theta)}. \quad (A14) \]
Thus, for the inter-band transitions \((ss' = -1)\), the transitions satisfying \( \Theta' + \Theta = \pi \), which are the forward scattering, have the largest matrix element squared. For the intra-band transitions \((ss' = 1)\), the transitions satisfying \( \Theta' + \Theta = 0 \), which are the forward scattering too, are allowed. The intra-band backward scattering satisfies \( \Theta' + \Theta = \pi \) and has vanishing matrix element.\(^{21}\)

The polarization characteristics of the absorption spectrum has been investigated for incident light energies up to 6 eV.\(^{22}\) The absorption peaks observed at 4.5 and 5.25 eV were found to exhibit different polarization dependencies. The behavior is also reproduced by our calculation, that is, peaks caused by \( E_{||} \) and \( E_{\perp} \) appear approximately at 5 and 6 eV, respectively, as shown in Fig. 10. The discrepancy between experiment and calculation may be attributed to the fact that we have ignored the overlap between the wavefunctions at nearest neighbor \( \pi \) electrons giving asymmetry in the conduction and valence bands.\(^{23}\) The qualitative agreement suggests the correctness of the optical matrix elements used to evaluate the dynamical conductivity. Note that the peak structure of \( \text{Re}(\tilde{\sigma}_{\perp}) \) at about 6 eV may be regarded as a plasmon resonance because \( \text{Im}(\tilde{\sigma}_{\perp}) \) has a peak structure at the energy and \( \text{Re}(\tilde{\sigma}_{\perp}) \) approaches zero. Note also that a realistic doping level does not change these high-energy peaks and that the problem can be discussed simply in terms of the photo-electron interaction and the density of the electronic state.\(^{22}\)

It should be noted that the absorption coefficients of the optical matrix elements used to evaluate the dynamical conductivity. Note that the peak structure of \( \text{Re}(\tilde{\sigma}_{\perp}) \) at about 6 eV may be regarded as a plasmon resonance because \( \text{Im}(\tilde{\sigma}_{\perp}) \) has a peak structure at the energy and \( \text{Re}(\tilde{\sigma}_{\perp}) \) approaches zero. Note also that a realistic doping level does not change these high-energy peaks and that the problem can be discussed simply in terms of the photo-electron interaction and the density of the electronic state.\(^{22}\)
