ABSTRACT

Eukaryotic elongation factor 2 kinase (eEF2K) negatively regulates the elongation stage of mRNA translation and is activated under different stress conditions to slow down protein synthesis. One effect of eEF2K is to alter the repertoire of expressed proteins, perhaps to aid survival of stressed cells. Here, we applied pulsed stable isotope-labeling with amino acids in cell culture (SILAC) to study changes in the synthesis of specific proteins in human lung adenocarcinoma (A549) cells in which eEF2K had been depleted by an inducible shRNA. We discovered that levels of heat shock protein 90 (HSP90) are increased in eEF2K-depleted human cells, as well as in eEF2K-knockout (eEF2K−/−) mouse embryonic fibroblasts (MEFs). This rise in HSP90 coincided with an increase in the fraction of HSP90 mRNAs associated with translationally active polysomes, irrespective of unchanged total HSP90 levels. These results indicate that blocking eEF2K function can enhance expression of HSP90 chaperones.

In eEF2K−/− MEFs, inhibition of HSP90 by its specific inhibitor AUY922 promoted the accumulation of ubiquitinated proteins. Notably, HSP90 inhibition promoted apoptosis of eEF2K−/− MEFs under proteostatic stress induced by the proteasome inhibitor MG132. Up-regulation of HSP90 likely protects cells from protein folding stress, arising, for example, from faster rates of polypeptide synthesis due to the lack of eEF2K. Our findings indicate that eEF2K and HSPs closely cooperate to maintain proper proteostasis and suggest that concomitant inhibition of HSP90 and eEF2K could be a strategy to decrease cancer cell survival.

INTRODUCTION

Eukaryotic elongation factor 2 (eEF2) kinase (eEF2K) is an atypical protein kinase that phosphorylates eEF2 on Thr56 and renders it unable to interact with ribosomes. By reducing the availability of active eEF2, eEF2K slows down the elongation stage of protein synthesis (1), which consumes the vast majority of the energy used (>99%) by protein synthesis. eEF2K is activated under diverse cell stresses such as hypoxia (2), low pH (3), nutrient deprivation (4) and glycolytic stress (5), which are hallmarks of tumour microenvironments, and where saving energy or nutrients such as amino acids would benefit tumour cell survival. eEF2K knockout (eEF2K−/−) mice are healthy and viable (2), showing that eEF2K is not required for normal cell function under standard animal husbandry conditions. As such, it has been suggested that eEF2K inhibitors could hold therapeutic potential to treat some cancers, while exerting minimal on-target side effects.

Notably, we recently reported that accelerated translation rates lead to enhanced levels of translation errors, and that eEF2K serves to ensure accurate protein synthesis (6). In this study, using pSILAC (pulsed stable isotope-labelling with amino acids in cell culture) combined with LC-MS/MS analysis, we discovered that knocking down or deleting eEF2K in cells increases the translational efficiencies of HSP90 mRNAs. This may help cells to cope with higher levels of erroneously-translated and thus misfolded proteins. Strikingly, inhibition of HSP90 in eEF2K-null cells evoked apoptosis under conditions of proteolytic stress, suggesting that concomitant inhibition of HSP90 and eEF2K is detrimental to (cancer) cell survival.

RESULTS

Knock-down or knockout of eEF2K increases HSP90 expression

To assess whether eEF2K affects the synthesis of specific proteins under metabolic stress conditions, we applied the pSILAC (7) to label newly synthesized proteins metabolically and quantify their rates of (differential) accumulation by LC-MS/MS. A549 cells expressing an IPTG (isopropyl β-D-1-thiogalactopyranoside)-inducible shRNA against EEF2K were generated and treated with 2-
Disabling eEF2K elevates HSP90 under proteolytic stress

deoxyglucose (2-DG), a non-metabolisable glucose analogue which induces metabolic stress by inhibiting glycolysis, to activate eEF2K (5). They were subsequently incubated in culture medium containing heavy lysine and arginine isotopologs for 2 h to label ('mass-tag') newly-synthesized proteins (Fig. S1A). Proteins were extracted and subjected to trypsin digestion after which the resulting peptides were analysed by LC-MS/MS (Fig. S1B).

A total of 3,011 unique proteins were identified, of which the SILAC ratios of 973 proteins could reliably be quantified (See methods and Table S1). We detected 78 protein groups that differed in their synthesis rates (p-value < 0.01) upon knockdown of eEF2K (Fig. S1B). Further, synthesis of three members of the heat shock protein molecular chaperone family (HSPA5, HSP90B1 and HSP90AA1) were upregulated upon eEF2K knock-down (Fig. S1B). Of note, HSP90 proteins have been shown to interact with eEF2K, resulting in its stabilization (8). SDS-PAGE followed by Western blotting analysis confirmed the higher HSP90 protein expression levels in IPTG-treated A549 cells and eEF2K−/− MEFs compared to their vehicle-treated or wild-type counterparts, by 1.5 and 2.0-fold respectively. Also consistent with the pSILAC analysis, GAPDH levels were 1.6 and 2.3-fold lower in IPTG-treated A549 and eEF2K−/− MEFs respectively (Fig. S1C-E). In contrast, actin levels were unaltered (Fig. 1A). 2-DG treatment also led to a reduction in HSP90 protein levels in MEFs (Fig. 1D and E) (6). It was previously shown (9) that TOP mRNAs (mRNAs that contain a 5′-terminal oligopyrimidine tract, many of which encode ribosomal proteins and translation factors) are recruited onto polysomes upon activation of eEF2K, thereby causing an increase in the relative synthesis of TOP mRNA-encoded proteins compared to others. This feature was clearly evident in our pSILAC data, in good agreement with the findings of Gismondi et al. (9), thereby validating our own findings.

**eEF2K knockout shifts HSP90 mRNAs into polysomal fractions**

Higher HSP90 protein levels in eEF2K-null cells were not due to elevated levels of its mRNAs as, if anything, HSP90AA1 and HSP90B1 mRNA levels were slightly lower in eEF2K−/− MEFs (Fig. 2A and B). To study further how eEF2K regulates HSP90 protein expression, we fractionated lysates from 2-DG-treated eEF2K+/+ and eEF2K−/− MEFs through sucrose gradient profiling (Fig. 2C). 2-DG treatment greatly reduced the proportion of ribosomes in translationally-active polysomal fractions (Fig. S2). Interestingly, upon 2-DG induced eEF2K activation (Fig. 1D), the amounts of HSP90AA1 and HSP90B1 mRNAs associated with active polysomes were higher in eEF2K−/− MEFs than in WT cells, and their association with monosomal or sub-polysomal fractions was correspondingly lower (Fig. 2C-E). In contrast, the distribution of a ‘control’ mRNA, B2M (encoding β-2-microglobulin), was essentially unchanged (Fig. 2F). These data indicate that eEF2K negatively regulates the translation of HSP90 mRNAs by impairing mRNA association with polysomes.

**Concomitant inhibition of HSP90 and eEF2K induces protein ubiquitination and cell death**

Higher levels of HSP90 may help cells to maintain adequate protein folding under conditions of accelerated polypeptide synthesis (translation elongation) caused by the absence of eEF2K. Thus, blocking HSP90 function may be particularly detrimental to protein homeostasis (proteostasis) in cells lacking eEF2K. To test this, we exposed eEF2K+/+ and eEF2K−/− MEFs to MG132, a proteasome inhibitor, in the presence or absence of the HSP90 inhibitor NVP-AUY922 (hereafter called AUY922) (10). MG132 evokes phosphorylation of eEF2 (Fig. 3A), indicating activation of eEF2K. Under conditions of impaired protein degradation, ubiquitinated proteins first accumulate in the fraction that is soluble in 1% (v/v) Triton and then aggregate and relocate into the insoluble fraction (11).

As expected, after MG132 treatment, a large quantity of ubiquitinated proteins was found in clarified lysates and a slight increase in ubiquitinated proteins in 1% (v/v) Triton X-100-insoluble pellets was also observed (Fig. 3A-C). Inhibiting HSP90 activity by AUY922 increased levels of ubiquitinated proteins in the pellet fraction in eEF2K−/− MEFs, but the effect was considerably enlarged in eEF2K−/− cells (Fig. 3A-C), indicating a greater build-up of incorrectly folded proteins. Further, this was
Disabling eEF2K elevates HSP90 under proteolytic stress

accompanied with poly (ADP-ribose) polymerase (PARP) cleavage (Fig. 3A), indicating cell apoptosis (12).

We observed a reduction in protein refolding capacity in eEF2K−/− MEF lysates from cells pre-treated with MG132 and AUY922 (Fig. 3D), showing that HSP90 inhibition greatly impairs overall chaperone capacity in eEF2K-null cells. We also detected a large increase in early and late apoptotic AUY922-treated eEF2K−/− cells under proteotoxic stress induced by MG132 (Fig. 4) likely reflecting impaired proteostasis. Taken together, these data indicate that when elongation rates are enhanced, subsequent upregulation of HSP90 chaperone expression plays an important role in maintaining proteostasis.

DISCUSSION

Proteostasis involves tightly-regulated and balanced processes which are essential to cell and organ health span. The processes that modulate proteostasis include the synthesis, maturation and degradation of proteins. It follows that mRNA translation require effective mechanisms to ensure the correct folding and assembly of newly-synthesized polypeptides into functional proteins; dysregulation of this crucial process in cells contributes to development of protein misfolding disorders such as Alzheimer disease, Huntington disease and amyotrophic lateral sclerosis (ALS), among others (13).

Conn & Qian (14) and we (6) recently reported that mammalian target of rapamycin complex 1 (mTORC1) (6,14), ribosomal protein S6 kinases (S6Ks) (14) and eEF2K (6) function to optimise quality control during protein synthesis. For example, faster translation elongation resulting from eEF2K inhibition can lead to the production of mistranslated proteins (6) and, conversely, inhibition of mTORC1 by rapamycin slows down translation elongation resulting in more accurate translation (14). Faster elongation will increase the load of newly-synthesized polypeptides that need to be properly folded. Misfolded proteins are degraded, but is not clear how mTORC1 controls protein degradation (15,16); neither we (6) nor Conn and Qian (14) saw any detectable changes in chaperone capacity or proteasome activity upon inhibition of mTORC1 or eEF2K. However, because translation quantity is inversely related with quality, it is reasonable to speculate that alterations in translation speed and hence accuracy may also impact other proteostasis regulatory mechanisms to ensure proper protein production.

Previously, we showed that levels of certain proteins involved in cell migration are decreased upon eEF2K-knockdown in A549 cells (17). To measure the rates of de novo synthesis at the proteome-wide level, we applied pSILAC (which enables the identification and quantification of newly-synthesized proteins). Consistent with results from our study of steady-state protein levels (17), we only observed changes in the synthesis of a small proportion of proteins (78 out of the 973 quantifiable proteins) when comparing control and eEF2K knockdown cells (Fig. S1). Among them, levels of HSP90 chaperones were increased in A549 cells upon eEF2K knockdown and in eEF2K−/− MEFs (Fig. 1). This observation however, was not associated with increases in HSP90 mRNA levels, but instead resulted from increased translational efficiency of HSP-encoding mRNAs (HSP90AA1 and HSP90B1) (Fig. 2) overall, ensuring proper protein folding under accelerated rates of translation elongation. The mechanism by which depletion of eEF2K, and thus faster elongation, increases translation of HSP90 mRNAs is not clear. One possibility would be that their coding sequences contain rare codons, for which levels of the cognate tRNAs are low; this appears not to be the case. Another is that it relates to features of their 5'-UTRs (untranslated regions), regions which often control translation initiation. Notably, the HSP90 5'-UTR is known to possess extensive secondary structure (18) and may therefore make the translation of their mRNAs more susceptible to modulation during elongation, although the mechanisms that link control of elongation to modulation of initiation remain unclear [see (19)].

Conversely, suppressing HSP90 activity using AUY922 led to the accumulation of ubiquitinated proteins (Fig. 3) in eEF2K−/− cells and to apoptosis (Fig. 4), implying that eEF2K and HSP90 jointly act to maintain proper proteostasis. It has previously been reported that HSP90 physically interacts with
Disabling eEF2K elevates HSP90 under proteolytic stress

eEF2K, while disrupting the HSP90-eEF2K interaction by geldanamycin reduced eEF2K protein levels in glioblastoma cells (8), suggestive of the requirement of HSP90 for the proper folding and stability of eEF2K. Thus, eEF2K and chaperones such as HSP90 form a mutually complementary system to ensure proper protein folding and protection of cells against build-up of misfolded polypeptides.

Furthermore, given the growing interest in HSP90 and eEF2K inhibitors as anti-cancer agents, a combination therapy involving both types of inhibitors may offer a promising and effective strategy for therapy of some types of cancer.

EXPERIMENTAL PROCEDURES

Chemicals and reagents — All reagents were from Sigma-Aldrich (Castle Hill, NSW, Australia) unless specified. Bradford assay reagent was from Bio-Rad (Gladesville, NSW, Australia). IPTG was from Promega (Alexandria, NSW, Australia). AUY922 was kindly provided to us by Professor Lisa Butler (SAHMRI, Adelaide, SA, Australia) (20).

Cell culture, treatment and lysis — A549 (human lung carcinoma) cells expressing inducible short-hairpin RNA (shRNA) against eEF2K were generously provided by Janssen Pharmaceutica NV (Beerse, Belgium) (3). eEF2K-knockout mouse embryonic fibroblasts (MEFs) from eEF2K+/+ and eEF2K−/− mice (2) were prepared from embryos at embryonic day 13.5. The experimental procedures were approved by the South Australian Health & Medical Research Institute (SAHMRI)’s Animal Ethics Committee (ethics approval No. SAM220), and were carried out in accordance with the Australian code for the care and use of animals for scientific purposes (2013). Cells were cultured in high glucose (25 mM) DMEM (Dulbecco’s modified Eagle medium, Life Technologies, Scoresby, VIC, Australia) supplemented with 10% (v/v) fetal bovine serum (FBS) and 100 U/ml penicillin and 0.1 mg/ml streptomycin, and maintained at 37°C in humidified air with 5% (v/v) CO2. For pSILAC labelling, cells were cultured in low glucose (5.5 mM) DMEM (supplemented with dialysed FBS) containing 0.71 mM L-[13C]6-Arg and 0.41 mM L-[13C]6, [15N]2-Lys (Fig. S1A). To induce eEF2K knockdown, 5 days before sampling, 1 μM IPTG was added to A549 cells to induce expression of the shRNA against eEF2K. Control cells were treated with the corresponding vehicle. Cells were collected by trypsinization, washed twice with PBS (phosphate-buffered saline, Thermo Fisher Scientific) and lysed in ice-cold lysis buffer [1% (v/v) Triton X-100, 20 mM Tris-HCl (pH 7.5), 150 mM NaCl, 1 mM EDTA, 1 mM EGTA, 2.5 mM NaH2P2O7, 1 mM β-glycerophosphate, 1 mM dithiothreitol (DTT), 1 mM Na3VO4 and protease inhibitor cocktail (1x)]. Lysates were centrifuged at 16,000 x g and 4°C for 10 min and total protein concentrations in the supernatants quantified by Bradford assay. Where indicated, insoluble pellets were dissolved in 1x Laemmli sample buffer [62.5 μM Tris-HCl pH 6.8, 1% (w/v) SDS, 10% (v/v) glycerol, 10 μM DTT and 5 μg/ml bromophenol blue].

pSILAC labelling and LC-MS/MS analysis — As described in Fig. S1A, A549 cells were cultured in growth medium with or without IPTG (to induce shRNA eEF2K expression) for 5 days, medium was replaced by Arg/Lys-free DMEM for 1 h, cells were then incubated with 10 mM 2-DG for 1 h, before the addition of 0.71 mM L-[13C]6-Arg and 0.41 mM L-[13C]6, [15N]2-Lys and further incubation for 2 h. Cell (5 x 10⁶) pellets were resuspended in PBS with equal volumes of 8M guanidine chloride-HCl lysis buffer, lysed by three freeze-thaw rounds in liquid N2, and processed for LC-MS/MS analysis as described previously (21). All samples were introduced into an LC-MS/MS system through an Ultimate 3000 RSLC nano LC (Thermo Fisher Scientific, Bremen, Germany) in-line connected to a Q Exactive HF mass spectrometer (Thermo Fisher Scientific) (22).

Proteome data analysis — Raw data files were searched with MaxQuant (23) using the Andromeda search engine (version 1.5.4.1) (24) and MS/MS spectra searched against the Swiss-Prot database (taxonomy Homo sapiens; 20,198 entries; August 2016 version). Potential contaminants present in the contaminants.fasta file that comes with MaxQuant were automatically added. The precursor mass
Disabling eEF2K elevates HSP90 under proteolytic stress
tolerance was set to 20 ppm for the first search (used for nonlinear mass recalibration) and to 4.5 ppm for the main search. Trypsin/P (i.e. cleavages between lysine/arginine-proline residues were allowed) was selected as enzyme setting and up to two missed cleavages were allowed. Methionine oxidation was searched as fixed modifications, whereas N-terminal protein acetylation was set as variable modification. The false discovery rate for peptide and protein identification, estimated by using the reversed search sequences, was set to 1%, and the minimum peptide length was set to 7. The minimum score threshold for both modified and unmodified peptides was set to 40. The match between runs function with a match time window of 0.7 min and an alignment time window of 20 min was enabled and proteins were quantified by the MaxLFQ algorithm (25) integrated in the MaxQuant software. For SILAC ratio quantification, the re-quantification feature was enabled, multiplicity set at 2 and the relative quantification of the peptides against their SILAC-labelled counterparts (carrying +6Arg and/or +8Lys) was performed by MaxQuant. Only unique peptides were used for quantification and we required proteins being quantified with at least two ratio counts. For basic data analysis, normalization, statistics, and annotation enrichment analysis, the freely available open-source bioinformatics platform Perseus (version 1.5.3.2) (26) was used. Data analysis was done using the proteinGroups.txt file from MaxQuant. Potential contaminants as well as reversed sequences and proteins only identified by site (thus only by a peptide carrying a modified residue) were removed from the data set. The replicate samples were grouped and the normalized heavy over light protein ratios (i.e., in case of normalized protein ratios, the median of ratio sub-populations was shifted to 1) were log(2) transformed. A multiple-sample ANOVA test was applied with S0 parameter set to 0.1 and p-value threshold of 0.01 to assign proteins with significantly different pSILAC protein ratios between groups, thereby reflecting differential protein synthesis rates. Only proteins with minimally two valid quantification values (i.e. SILAC ratio’s) in at least one group were considered and missing values were imputed from a normal distribution around the detection limit (with 0.3 spread and 1.8 down-shift). Proteins with differential pSILAC ratios were selected for subsequent Z-score normalization and k-means clustering.

SDS-PAGE and Western blot (WB) analysis — Western blot analysis were performed as previously described (7). Primary antibodies used were: HSP90 (Sigma-Aldrich, #04-594); β-actin (Sigma-Aldrich, #A5316) eEF2 [New England Biolabs (NEB), Hitchin, Herts, UK, #2332]; ubiquitin (NEB, #3936); PARP (NEB, #9542); phosphorylated (P-) eEF2 Thr56 and eEF2K (custom made by Eurogentec, Seraing, Belgium). Fluorescently-tagged secondary antibodies were from Thermo Fisher Scientific. Blots were scanned using a LiCor Odyssey imaging system (Millenium Science, Mulgrave, VIC, Australia).

Real-time quantitative RT-PCR (qPCR) amplification analysis — Total RNA was extracted using TRIzol (Life Technologies). cDNA was produced using the ImProm-II reverse transcription (RT) system (Promega) with oligo(dT)15. For qPCR analysis of sucrose gradient fractions, 1.2 kb kanamycin RNA provided by the RT kit was used as an internal control. qPCR was performed using the following primers (5’-3’): mouse HSP90AA1: forward: CTGACGGACCCCAGTAAACT, reverse: CCTGCAAAGCCCTCCATGAAG; HSP90B1: forward: AGTCGGGAAGCAACAGAGAA, reverse: TCTCCATGTTGCCAGACCAT; B2M: forward: CTGCTACGTAACACAGTTCCACCC, reverse: CATGATGCTTGATCACATGTCTCG. Samples were analysed with SYBR green dye mix (Life Technologies) on an ABI Step One Plus qPCR instrument (Applied Biosystems, Cheshire, UK). For total RNA analysis, B2M was used as the normalisation control. The comparative threshold cycle (CT) method was applied to quantify mRNAs present in each sample.

Polysome analysis — Performed as previously described (7). For RNA extraction, 1% (w/v) SDS and 0.15 mg/ml proteinase K were added to each fractions, 1:3 (v/v) phenol:chloroform pH 4.5 was then added to the samples to extract RNA, RNA were precipitated from the aqueous phase by the addition of 70% (v/v) isopropanol. RNA pellets were washed once with 80% (v/v) ethanol, before dissolving in RNase/DNase-free water for further analysis.
In vitro refolding assay — Recombinant firefly luciferase (Fluc) (Promega) was diluted in lysis buffer at 50 μg/ml and then denatured at 42°C, 1000 rpm for 15 min. Denatured Fluc was added to cell lysates for a final concentration of 16.5 μg/ml. Refolding was conducted at room temperature and 1000 rpm for the indicated periods of time. Fluc activity was monitored with luciferase reporter assay system (Promega) on a Glomax Discover multimode microplate reader (Promega) following the manufacturer’s instructions. Fluc activity in lysis buffer alone was used as a control to exclude spontaneous refolding of denatured Fluc.

Annexin V / propidium iodide (PI) staining — Following culture media removal, the cells were washed once with PBS, then incubated in 1X trypsin/EDTA (0.5%) for 1 min at 37°C. Growth medium was added and the cells were gently dispersed by pipetting and centrifuged at 200 x g for 5 min at room temperature. The medium was removed and Annexin V / PI staining performed using the Annexin-V-Fluos staining kit according to the manufacturer’s instructions. The intensity of fluorescence signals was recorded using FACScantoTM II flow cytometry [Becton Dickinson (BD) Biosciences, Wayville, SA, Australia], data were analysed using FlowJo software version 10.2 (BD Biosciences).

Statistical analysis — Statistical analysis were performed using a one-way or two-way ANOVA with an unpaired student t test with the means of three independent experiments unless otherwise specified. Data are presented as means ± S.D., GraphPad Prism software was used to calculate p-values. *: 0.01 ≤ p < 0.05; **: 0.001 ≤ p < 0.01; ***: p < 0.001.

ACKNOWLEDGEMENTS
We would like to thank Dr. Randall H. Grose from ACRF Innovative Cancer Imaging Facility at SAHMRI for his technical support and Prof. Kris Gevaert from the VIB Center for Medical Biotechnology for financial support of this research.

FIGURE LEGENDS

FIGURE 1. Knocking down or ablating eEF2K elevates HSP90 protein levels. A, Lysates of A549 cells treated -/+ IPTG (to induce shRNA expression to knockdown eEF2K) or eEF2K+/+ and eEF2K-/- MEFs were subjected to SDS-PAGE followed by WB analysis of the indicated proteins. B, C Quantification of HSP90 levels in A549 cells (B) or MEFs (C) from A. D, eEF2K+/+ and eEF2K-/- MEFs were cultured in low glucose (5.5 mM) DMEM -/+ 10 mM 2-DG for 24 h before immunoblotting analysis. E, Quantification of HSP90 levels from D.

FIGURE 2. eEF2K knockout in MEFs shifts HSP90AA1 and HSP90B1 mRNAs from polysomal to non/sub-polysomal fractions. A and B, eEF2K+/+ and eEF2K-/- MEFs were treated as in Fig. 1E, total cell mRNA was extracted and subjected to qPCR reaction with primers for HSP90AA1 (A) and HSP90B1 (B). C-F, eEF2K+/+ and eEF2K-/- MEFs were treated as in Fig. 1E, cell lysates were subjected to polysome analysis. A representative profile is shown in C and positions of ribosomal/polysomal species are indicated. RT-qPCR was performed using specific primers for mouse HSP90AA1 (D), HSP90B1 (E) and B2M (F).

FIGURE 3. AUY922 increases levels of ubiquitinated proteins in 1% (v/v) Triton-insoluble pellets from eEF2K-/- MEFs. A-C, eEF2K+/+ and eEF2K-/- MEFs were cultured with vehicle, 50 nM AUY922 or/and 3 μM MG132 for 24 h. Clarified cell lysates and detergent-insoluble pellets were subjected to SDS-PAGE followed by WB analysis of the indicated proteins (A). Levels of ubiquitin (Ub) in clarified lysates (B) and insoluble pellets (C) were quantified. D, MEFs were treated as in A, and cell lysates incubated with previously heat-denatured Fluc at room temperature. Fluc refolding was assessed by measuring Fluc activity at the indicated time points.

FIGURE 4. AUY922 induces apoptosis in eEF2K-/- MEFs under proteolytic stress. eEF2K+/+ and eEF2K-/- MEFs were treated as in Fig. 3A. A, cell viability and morphology assessed by microscopic analysis. Scale bar = 500 µm. B, Cells were dispersed, stained with annexin V (FITC-A) and PI (PI-A), and then analysed by flow cytometry. C, Quantification of B.
