In this study, we investigated an alternative method for the chemical CO$_2$ reduction reaction in which power ultrasound (488 kHz ultrasonic plate transducer) was applied to CO$_2$-saturated (up to 3%) pure water, NaCl and synthetic seawater solutions. Under ultrasonic conditions, the converted CO$_2$ products were found to be mainly CH$_4$, C$_2$H$_6$ and C$_3$H$_8$, including large amount of CO which was subsequently converted into CH$_4$. We have found that introducing molecular H$_2$ plays a crucial role in the CO$_2$ conversion process and that increasing hydrogen concentration increased the yields of hydrocarbons. However, it was observed that at higher hydrogen concentrations, the overall conversion decreased since hydrogen, a diatomic gas, is known to decrease cavitational activity in liquids. It was also found that 1.0 M NaCl solutions saturated with 2% CO$_2$ + 98% H$_2$ led to maximum hydrocarbon yields (close to 5%) and increasing the salt concentrations further decreased the yield of hydrocarbons due to the combined physical and chemical effects of ultrasound. It was shown that CO$_2$ present in a synthetic industrial flue gas (86.74% N$_2$, 13% CO$_2$, 0.2% O$_2$ and 600 ppm of CO) could be converted into hydrocarbons through this method by diluting the flue gas with hydrogen. Moreover, it was observed that in addition to pure water, synthetic seawater can also be used as an ultrasonicating media for the sonochemical process where the presence of NaCl improves the yields of hydrocarbons by ca. 40%. We have also shown that by using low frequency high-power ultrasound in the absence of catalysts, it is possible to carry out the conversion process at ambient conditions i.e., at room temperature and pressure. We are postulating that each cavitation bubble formed during ultrasonication act as a “micro-reactor” where the so-called **Sabatier reaction** $\text{CO}_2 + 4\text{H}_2 \xrightarrow{\text{Ultrasonication}} \text{CH}_4 + 2\text{H}_2\text{O} -$ takes place upon collapse of the bubble. We are naming this novel approach as the “Islam-Pollet-Hihn process”.

1. Introduction

CO$_2$ is the major contributor to global climate change. Around 80–90% of the total global CO$_2$ emission comes from fossil fuel combustion. This emission has been increasing by 2.7% annually over the past decades [1]. The CO$_2$ levels have risen above 400 ppm and it is thought that it will not decrease for many years. The scientific consensus is that these emission levels are unsustainable and must be curbed if mankind is to avoid irreparable damage to global ecosystems [2]. Immense research and investment have been carried out for efficiently capturing CO$_2$ and converting it into useful hydrocarbon fuels since the early 21st century [3].

Conversion of CO$_2$ into hydrocarbons is of specific interest since this pathway can contribute to minimizing climate change while obtaining valuable products. There are several possible methods for turning CO$_2$ into a fuel, including chemical, photochemical, electrochemical (CO$_2$RR - electrochemical CO$_2$ reduction reaction) and biochemical methods [3]. Although, most of these methods are energy intensive and less efficient to be economically viable. Industrially, the most widely used method to convert CO$_2$ into hydrocarbons, is called the **Sabatier reaction**, also known as the **Sabatier process**.

Sabatier and Senders introduced this reaction first time in the beginning of the 20th century. It was mainly used to remove CO$_2$ from the feed gas from ammonia synthesis. Recently hydrogen (H$_2$) has gained renewed interest in the field of power-to-gas (P2G) technology. According to the Sabatier reaction, one mole of CO$_2$ reacts with four.

moles of H$_2$ to produce one mole of methane. This synthetic route is
renewable and sustainable if the required hydrogen is produced via
water electrolysis using renewable electricity such as hydro, wind or
solar power. This is an exothermic reaction and the stoichiometry is
shown in equation (1) [4].

\[
CO_2 + 4H_2 \leftrightarrow CH_4 + 2H_2O \quad \Delta H_{298}^0 = -165 \text{ kJ/mol} \tag{1}
\]

This strongly exothermic reaction is accompanied by a mildly
endothemic reverse water–gas shift reaction (2) and an exothermic CO
methanation (2) [4–6].

\[
CO_2 + H_2 \leftrightarrow CO + H_2O \quad \Delta H_{298}^0 = +41 \text{ kJ/mol} \tag{2}
\]

\[
3H_2 + CO \leftrightarrow CH_4 + H_2O \quad \Delta H_{298}^0 = -206 \text{ kJ/mol} \tag{3}
\]

The overall process is very exothermic, and the reaction is favored at
lower temperatures. However, at low temperatures, the reaction kinetics
are poor, and a catalyst needs to be used to overcome the kinetic limi-
tations. Different catalysts have been employed for the methanation
reaction such as, Ni, Ru and Rh. Nickel (Ni) is the most widely used
catalyst due to its high selectivity towards methane and its low cost. The
operating temperature for Ni-based catalyst are usually kept below
550 °C in order to prevent catalyst deactivation.

However, the Sabatier process is an energy intensive process. In
order to overcome this energy dependency on CO$_2$ fixation, many other
processes have evolved over the last few decades. These processes are
mainly the electrochemical CO$_2$ conversion [7], photocatalytic conver-
sion [8], modified Fischer-Tropsch (FT) [9] and the biochemical routes
[10,11]. All these methods have advantages and disadvantages and
depend upon the nature of the CO$_2$ input, that is, its purity and tem-
perature. In the search of an energy efficient CO$_2$ conversion process, we
have investigated the possibility to use power ultrasound to convert CO$_2$
into hydrocarbons at ambient conditions i.e., at room temperature and
pressure and without using any catalytic materials.

It is well-known that when a liquid, such as water, is subjected to
ultrasound in the range of 20 kHz to 1 MHz, microscopic bubbles also
known as cavitation bubbles are formed. Cavitation bubble collapse
leads to near adiabatic heating of the vapour that is trapped inside the
bubble creating the so-called “hotspot” in the fluid where high tem-
peratures (ca., 5,000 K) and high pressure (ca. 2,000 atm) are generated.
At these extreme conditions, water vapour is ‘pyrolyzed’ into hydrogen
(H) and hydroxyl radicals (OH) known as water sonolysis. However, it
was observed that the production of radicals is ultrasonic frequency
dependent and it was found that the yield of radicals are maximum in
the range 340–500 kHz [12]. We speculate that the millions of cavitation
bubbles produced by ultrasonication may act as micro-reactors where
Sabatier reaction can take place in the presence of hydrogen which are
produced during the sonolysis of water or supplying excess hydrogen
into the system via water electrolysis [13]. In this study, we present the
proof of this concept through rigorous experimental procedures
addressing the key parameters that govern the Sabatier reactions at
ambient conditions under power ultrasound. We have named this novel
approach as the “Islam-Pollet-Hihn process” which is an ultrasound-
asisted Sabatier process at ambient conditions and in absence of a
catalyst.

2. Experimental

2.1. Experimental reactor setup

The CO$_2$ conversion experiments were performed using a 488 kHz
ultrasonic transducer of 70 mm diameter manufactured by Honda
Electronics Co., LTD. The ultrasound emitting surface area is approxi-
mately of 1.54 cm$^2$. This transducer is fitted to a specially designed glass
reactor of 523 ml volume. The reactor has an inner diameter of 70 mm
which is equal to the transducer diameter. The outer diameter of the
reactor is 110 mm. The outer space is used as the cooling jacket in order
to ensure efficient cooling. The reactor is then clamped with the trans-
ducer support. A silicon sheet of 0.5 mm thickness is placed in between
the glass reactor and transducer support in order to ensure complete
sealing (Fig. 1).

The inner vessel of the reactor has two ports. One port equipped with
an NS14 glass joint which is used to insert a glass tube inside the reactor

Fig. 1. Schematic illustration of the experimental setup. Here, MFC = Mass Flow Controller, GC = Gas Chromatograph.
for gas bubbling. Another port is equipped with a GL10 thread. A screw cap with rubber septa is used to close this port. Gas samples for Gas Chromatography (GC) analysis were collected through the rubber septa using a Hamilton gas tight syringe (1000 series, 1 ml inner volume) equipped with SampleLock feature.

Three Mass Flow Controllers (MFC) from Alicat Scientific were used for mixing the gases in desired composition. The inlet of the MFCs were connected with the central gas reservoir or gas cylinders such as flue gas/calibration gas. The outlet of the each MFCs were connected with a gas mixture in order to ensure efficient mixing of the desired gases before entering into the reactor. The output pressure of the MFCs were set to 1,100 mbar which was also equal to the reactor pressure. A gate valve was placed in between the gas mixture and the inlet of the reactor in order to ensure air tightness inside the reactor.

For the sono-CO$_2$ conversion experiments, ultrapure water (18.2 MΩ), NaCl (ACS reagent > 99.0%, Sigma Aldrich) solution of different concentrations and synthetic seawater was used as ultrasonication media. The synthetic seawater was prepared according to the chemical components reported by Kester et al. [14] which has a salinity of 35. The components of the synthetic seawater are presented in Table 1. Synthetic flue gas was purchased from Linde which was composed of 86.74% N$_2$, 13% CO$_2$, 0.2% O$_2$ and 600 ppm of CO.

At first, 200 ml of solution was transferred into the reactor and then desired gas compositions were bubbled into the water for 30 min by keeping the outlet port (GL10 threaded) marginally open. After 30 min, the outlet port was completely closed. As soon as the reactor pressure had reached 1,100 mbar, the inlet valve was also closed ensuring a complete airtight system. After that, the ultrasonication started and lasted for 1 h. After 1 h of ultrasonication, gas samples were collected and injected into the GC for analysis. The liquid samples were also collected and analyzed by High Performance Liquid Chromatography (HPLC).

### 2.2. Dosimetry and calorimetry study

The “Weissler dosimetry” (potassium iodide – KI dosimetry) was performed at 5 °C for the ultrasonic frequencies of 20, 210, 326, 408 and 488 kHz according to the method explained by Iida et al. [15]. At 488 kHz frequency, the Weissler dosimetry was performed at four different gas saturations such as CO$_2$, H$_2$, N$_2$ and Ar. 200 ml of 0.10 M KI were ultrasonicated for 10 min. Prior to ultrasonication, the solution was bubbled for 10 min with the respective gas. After 10 min of ultrasonication, aliquots of 1 ml were collected and analyzed using a UV–vis spectrophotometer (GENESYS 30, Thermo Scientific).

To calculate the Sonochemical Efficiency (SE), acoustic powers ($P_{acoustic}$) were determined by the calorimetric method, according to Mason et al. [16] and Contamine et al. [17]. SE [μmol/kJ] was calculated according to equation (4) [15].

$$SE = \frac{CV}{P_{acoustic}t} \tag{4}$$

Here, $C$ [μM] is the concentration of $I_2$, $V$ [L] is the solution volume, $P_{acoustic}$ [kW] is the acoustic power and $t$ [s] is the ultrasonication time.

### 2.3. CO$_2$ conversion product analysis

The gaseous products were analyzed using an SRI GC (Model 8610C). The GC was equipped with 3 HayeSep D Pack columns (8600-FKDB 6′ x 1/8′′ S.S) with a total length of 18 feet connected in series. Both FID (Flame Ionization Detector) and TCD (Thermal Conductivity Detector) detectors were used to identify and quantify all the gases. The FID was used mainly for analyzing the hydrocarbons such as CH$_4$, C$_2$H$_4$, and C$_2$H$_6$ and the sensitivity of the detector was set to “HIGH”. The TCD detector was used for analyzing the H$_2$, O$_2$, N$_2$, CO, and CO$_2$. Argon (Ar) was used as carrier gas in the GC. GC was calibrated in a three-point calibration. Different calibration gas mixtures were prepared using the MFCs and injected into the GC for constructing the calibration curve. Then the reaction samples were analyzed against the performed calibration curve. Before analyzing the unknown reaction samples, a known concentration of gas was injected each time in order to check the accuracy of the analysis.

The liquid samples were analyzed using a Shimadzu Prominence i series compact HPLC (LC-2030C 3D Plus). The HPLC was equipped with a Shodex SUGAR SH1011 column including two detectors. The detectors were a PDA (Photodiode Array) and a RID (Refractive Index Detector). The HPLC analysis was performed in an isotropic method with the mobile phase (5 mM H$_2$SO$_4$) at a flow rate of 0.8 ml/min. For calibration of the HPLC, a stock mixture solution made of 0.05 M of ethanol, methanol, formic acid and acetic acid was prepared. Two more samples of 0.01 M and 0.025 M were prepared by diluting the 0.05 M stock solution. The three known concentration samples were then analyzed for constructing the three-point calibration graph. The unknown reaction samples were then analyzed against the calibration curve.

### 2.4. Carbon-based conversion and yield calculations

To study the sonochemical CO$_2$ conversion, the overall carbon-based conversion efficiency and yield of CO$_2$ converted products were used as figures of merit according to the equations (5) and (6). Carbon-based overall conversion efficiency is the amount of initial carbon in the form of CO$_2$ (both gaseous and dissolved in the solution) that is converted into products after 1 h of ultrasonication. Carbon-based yield of products is the amount of carbon present in the product from the initial amount of the total carbon.

**Carbon-based overall conversion efficiency:**

$$X_{CO_2} = \frac{(m_{CO_2(g)} + m_{CO_2(dissolved)})_{t=0} - (m_{CO_2(g)} + m_{CO_2(dissolved)})_{t=1h}}{(m_{CO_2(g)} + m_{CO_2(dissolved)})_{t=0}} \times 100 \tag{5}$$

**Carbon-based yield:**

$$Y_i = \frac{(m_{i(gas)} + m_{i(dissolved)})_{t=0} - (m_{i(gas)} + m_{i(dissolved)})_{t=1h}}{(m_{i(gas)} + m_{i(dissolved)})_{t=0}} \times 100 \tag{6}$$

Here, $m_{CO_2(g)} = mass$ of carbon in gaseous CO$_2$,

$m_{CO_2(dissolved)} = mass$ of carbon in dissolved CO$_2$,

$m_{i(gas)} = mass$ of carbon in the product $i$ in gaseous state.

$m_{i(dissolved)} = mass$ of carbon in the product $i$ in dissolved state.

The gas concentration in the gaseous state was measured using the gas chromatograms. The amount of dissolved gases was estimated using the Van’t Hoff equation (7) and Henry’s law (8) [18].

$$H(T) = H_{ref} \times e^{(\frac{-K\cdot T}{H_{ref}})} \tag{7}$$

$$c_i = \frac{p_i}{H(T)} \tag{8}$$

Here, $H(T) = Henry$ constant at temperature $T$, $H_{ref} = Henry$ constant at reference temperature (at STP)

---

**Table 1**

List of components in synthetic seawater for a salinity of 35.

| Salts        | Concentration (g/L) | Molar concentration (M) |
|--------------|---------------------|-------------------------|
| NaCl         | 23.93               | 0.4096                  |
| MgCl$_2$     | 5.079               | 0.0249                  |
| Na$_2$SO$_4$ | 3.994               | 0.0281                  |

| NaHCO$_3$    | 0.196               | 0.00233                 |
sonic transducers of different frequencies were studied. The energy-

Fig. 2. Effect of ultrasonic frequency on the sonochemical activity.

conversion efficiency and yield of different products were calculated.

Fig. 3. Effect of dissolved gases on the sonochemical activity (488 kHz).

\[ K = \frac{-\Delta H}{C_i p_i} = \text{constant} \]

\[ C_i = \text{Molar concentration of the dissolved gas } i \]

\[ p_i = \text{Partial pressure of the dissolved gas } i \]

After 1 h of ultrasonication, the liquid samples were also collected and analyzed by HPLC. A trace amount of ethanol was found in the liquid samples through the HPLC analysis. However, since the quantity is very small, it was not taken into the consideration when the overall conversion efficiency and yield of different products were calculated.

3. Results and discussion

In order to choose the right frequency for the sonochemical CO\textsubscript{2} conversion experiment, at first the sonochemical activity of the ultrasonic transducers of different frequencies were studied. The energy-specific yield of radicals due to ultrasonication at different frequency is shown in Fig. 2. The transmitted acoustic power \( P_{\text{Acoustic}} \) at 20 kHz (50% amplitude) was found to be the maximum (81.55 ± 0.62 W). The lowest acoustic power (11.78 ± 1.15 W) was found at 210 kHz, and according to equation (4), sonochemical efficiency was maximum at that frequency. On the other hand, the triiodide concentration was found to be maximum at 488 kHz (49.23 μM). This value was ca. three times higher than the value obtained from the 20, 326 and 408 kHz ultrasonic transducers. In addition, the triiodide concentration was five times higher at 488 kHz than at 210 kHz. At this stage of this study, the main focus was to find a sonochemical system with yielded the highest cavitation activity instead of the highest SE. Therefore, the 488 kHz transducer was chosen for all sonochemical CO\textsubscript{2} conversion experiments.

In addition, the cavitation activity in both diatomic and monoatomic gases at 488 kHz was studied and the results are presented in Fig. 3. It was found that the monoatomic gases such as argon (Ar) exhibited the maximum sonochemical efficiency due to its higher polytropic ratio \( \gamma = 1.66 \) and lower thermal conductivities \( \lambda = 0.018 \text{ W/m/K} \) compared to N\textsubscript{2} \( \gamma = 1.405, \lambda = 0.0167 \text{ W/m/K} \) [13]. However, hydrogen plays a unique role in sonochemical CO\textsubscript{2} conversion which is further explained in section 3.1. On the other hand, cavitational activity in the presence of dissolved CO\textsubscript{2} is suppressed almost entirely. Therefore, sonochemical reduction of CO\textsubscript{2} can be carried out only by mixing with other gases such as Ar, N\textsubscript{2} or H\textsubscript{2}.

3.1. Effect of hydrogen gas concentration

Since, in CO\textsubscript{2}-saturated solutions, cavitation activity is quenched almost entirely, a mixture of CO\textsubscript{2} with Ar and H\textsubscript{2} was chosen for the sono-CO\textsubscript{2} conversion experiments. In order to understand the mechanism of the sono-CO\textsubscript{2} conversion process, 2% CO\textsubscript{2} was mixed with three different H\textsubscript{2} concentrations and ultrasonicated for one hour using pure water as ultrasoninating media at 5 °C. In the first set of experiments, no hydrogen (0%) was used but 2% CO\textsubscript{2} was mixed with 98% Ar. In the second set of experiments, 2% CO\textsubscript{2} was mixed with 20% H\textsubscript{2} and 78% Ar. In the third set of experiments, 2% CO\textsubscript{2} was mixed with 60% H\textsubscript{2} and 38% Ar and the last set of experiments was performed with 2% CO\textsubscript{2} and 98% H\textsubscript{2}. The experimental findings are presented in Fig. 4. It was observed that the conversion efficiency increased with increasing hydrogen concentration from 0 to 60%. However, the conversion efficiency drastically decreased when the hydrogen concentration was 98%. It was found that the main sono-CO\textsubscript{2} reduced product was CO which also followed the same trend as the conversion efficiency.

On the other hand, the yield of hydrocarbons such as CH\textsubscript{4}, C\textsubscript{2}H\textsubscript{4}, and C\textsubscript{2}H\textsubscript{6} increased with increasing hydrogen concentration. A CH\textsubscript{4} yield of 2.7% was observed when a mixture of 2% CO\textsubscript{2} and 98% H\textsubscript{2} was ultrasonicated at 5 °C. When no hydrogen (0%) was used (2% CO\textsubscript{2} + 98% Ar), only a trace amount (0.003% yield) of methane was observed. It is possible that during bubble collapse, \textit{in-situ} produced hydrogen through water sonolysis [13], reacts with CO\textsubscript{2} producing CH\textsubscript{4} according to the Sabatier reaction. When 20% H\textsubscript{2} is added and 20% Ar is reduced, the yield of CH\textsubscript{4} was found to be only 0.03%. The ratio between CO\textsubscript{2} and H\textsubscript{2} was found to be 1:10 which is larger than the Sabatier reaction ratio (1:4). However, when only hydrogen is used with 2% CO\textsubscript{2}, CH\textsubscript{4} yield increased drastically. Therefore, hydrogen works not only as a hydrogen donor to fulfill the Sabatier ratio, but it also acts as a reducing agent.

Gutierrez et al. [19] studied for the first time the effect of hydrogen atom, H\textsubscript{i}, in the sonolysis of aqueous solution. They observed that under argon atmosphere, the primary step in the sonolysis of water follows reaction (9).
M.H. Islam et al.

Effect of CO₂ concentration on the sonochemical conversion of CO₂ at 5 °C in pure water.

\[ H_{2}O \rightarrow H + OH \]  \hspace{1cm} (9)

However, when hydrogen is present in the system, the hydroxyl radicals (OH•) are scavenged by hydrogen leaving the H• agent free according to the reaction (10)

\[ OH + H_{2} \rightarrow H_{2}O + H \]  \hspace{1cm} (10)

OH• is an oxidizing agent whereas H• is a reducing agent. During ultrasonication in the hydrogen atmosphere, the continuous removal of OH• creates an overall reducing environment in the system. Recently, Islam et al. [20] postulated that the extreme conditions caused by the cavitation bubble collapse may trigger the homolytic fission of H₂ molecule producing higher amount of H•.

\[ H_{2} \xrightarrow{\text{Ultrasonication}} H + H \]  \hspace{1cm} (11)

Due to the creation of this reducing environment, CO₂ reduction is facilitated producing more reduced products such as carbon monoxide and hydrocarbons. From Fig. 4, we observe that there is a maximum present in the reduction of CO₂ to CO at around 50% H₂. With increasing H₂, more OH• radicals are scavenged by hydrogen that would re-oxidize the reduced products such as CO and hydrocarbons formed by H• attack. The increase in gas content within the liquid leads to a lower cavitation threshold and intensity of the shock wave released on the collapse of the bubble. It has been observed that the use of monoatomic gases (e.g., He, Ar, Ne) provides more effective cavitation than diatomic gases (e.g., N₂, O₂, air). However, molecular hydrogen is a diatomic gas. Increasing the concentration of a diatomic gas usually decreases the overall cavitation activity in the system due to adiabatic compression during bubble collapse. We can observe this phenomenon from the dosimetry study presented in Fig. 3. Due to these two-opposing effects, we may see a maximum point on the conversion of CO₂ and the yield of CO in Fig. 4.

On the other hand, the yield trends of hydrocarbon have an opposite behavior whereby rising H₂ increases gradually the yields of hydrocarbons. Two possible reasons for this behaviour can be addressed as follows. One reason is the higher amount of available H• with increasing hydrogen concentration. Another reason is the lack of OH• which could re-oxidize hydrocarbons back to CO₂. Therefore, if one wants to convert CO₂ into hydrocarbons, then higher hydrogen concentration is the optimal option. If one wants to reduce CO₂ into CO, then an equal mixture of Ar and H₂ would provide the maximum yield.

3.2. Effect of CO₂ concentration

The effect of CO₂ concentration on the sono-CO₂ reduction was studied and the results are presented in Fig. 5. In this set of experiments, 2%, 5%, 8% and 13% CO₂ were mixed with 98%, 95%, 98% and 87% H₂ and was ultrasonicated for 1 h at 5 °C using pure water as sonicating media. It was found that increasing CO₂ concentrations decreased CO₂ conversion efficiency and CO yield, and the yields of hydrocarbons also gradually decreased. For example, increasing the CO₂ concentration from 2% to 5% decreased the yield of CH₄ from 2.7% to 0.13%. At 13% CO₂ concentration, a very trace amount (8 × 10⁻⁴%) of CH₂ yield was observed. Conversion efficiencies also decreased from 41% to 0.88% when CO₂ concentration increased from 2% to 13%.

These findings suggest that CO₂ concentration has an effect on the cavitational activity. Even the presence of 13% CO₂ can almost completely quench the acoustic activity in the system. Dosimetry study (Fig. 3) also revealed a similar observation where very negligible values of sonochemical efficiency was obtained when 0.10 M KI solution was ultrasonicated. These findings are in very good agreement with those obtained by Merouani et al. [21] and Kerboua et al. [22] who studied the mechanism of pure CO₂-quenching sonochemical processes through numerical method. They claimed that CO₂ may reduce or even suppress the yield of OH radicals from a single acoustic bubble. This is mainly due to the very high solubility of CO₂ (46-fold higher than air) in the solution compared to other traditional gases used in sonochemistry. Due to its high solubility, bubble–bubble coalescence occurs more in the presence of CO₂ than other gases, as well as the presence of these large bubbles reduces drastically the cavitational activity. Thus, CO₂-saturation may lead to total disappearance of chemical activity. Therefore, in order to avoid bubble–bubble coalescence, a low concentration of CO₂ is beneficial for carrying out any sonochemical effects. According to Fig. 5, a CO₂ concentration less than 3% is “ideal” for conversion of CO₂ into hydrocarbons.

3.3. Effect of temperature

2% CO₂ mixed with 98% H₂ in water was ultrasonicated for 1 h at temperatures of 5, 10, 20 and 30 °C and the conversion efficiencies, CO yields and hydrocarbon yields were generated as shown in Fig. 6. It can be observed that increasing temperature decreases the conversion efficiency, yields of CO and hydrocarbons. Almost a 50% decrease in the methane yield is observed by just increasing the temperature from 5 °C to 10 °C. These findings suggest that CO₂ conversion to hydrocarbons is favorable at low temperatures. A temperature ranges from 2 to 5 °C is advantageous since operating below these temperatures has the risk of freezing the solution when pure water is used, for example.

The reason for the deterioration of the sono-CO₂ process with increasing temperature can be attributed to the basic principle of sonochemistry in pure water. Increasing temperature decreases the polytropic index (γ) of gases, and when the liquid temperature increases, it causes less violent collapse of the cavitation bubble due to the decrease...
of the polytropic index. Less violent collapse leads to lower internal bubble temperatures. Lower internal bubble temperature lowers the formation of free radicals by the decomposition of water i.e. sonolysis [13]. In addition, quantity of water vapour trapped inside the bubble formation of free radicals by the decomposition of water i.e. sonolysis bubble temperatures. Lower internal bubble temperature lowers the lower when compared to our reference point (2% CO\textsubscript{2} conversion process. The yield of methane from diluted flue gas was still very negligible (0.88%) at 13% CO\textsubscript{2} conversion efficiency was found to be 15% with a methane yield of 9.2%. In addition, hydrocarbon with higher carbon concentration in the mixed gas dropped from 13% to 3% which was close to the threshold maximum limit of a meaningful sono-CO\textsubscript{2} conversion process. The yield of methane from diluted flue gas was still lower when compared to our reference point (2% CO\textsubscript{2} + 98% H\textsubscript{2}). This interesting finding could be due to the presence of an additional diatomic gas (N\textsubscript{2} > 80%) which lowered the global cavitation activity. In other words, and from our conditions, CO\textsubscript{2} conversion using ultrasound from 100% flue gas in water is not feasible. However, mixing the flue gas with H\textsubscript{2} to maintain the CO\textsubscript{2} concentration lower than the threshold concentration (3%) increases the CO\textsubscript{2} conversion efficiency and yield of hydrocarbons significantly.

### 3.5. Effect of NaCl concentration and synthetic seawater

The effect of NaCl concentration on the sono-CO\textsubscript{2} conversion process was investigated using 2% CO\textsubscript{2} and 98% H\textsubscript{2} gas mixture at 5°C. Various NaCl concentrations (0.40 M, 1.00 M, 3.00 M and 5.00 M) were used along with pure water as “reference” and the results are presented in Fig. 8. NaCl concentrations have a complex effect on the sono-CO\textsubscript{2} process. It may be observed that the conversion efficiency increased with increasing NaCl concentration up to 3.00 M and then drastically decreased at 5.00 M. However, the yields of hydrocarbons showed a different trend whereby the yield increased up to 1.00 M and then started decreasing with increasing salt concentration. At 1.00 M NaCl concentration, the yield of methane had a maximum at around 4.2%. These observations can be explained through the study by Pflieger et al. [23] where they studied the effect of NaCl concentration on the sonochemistry and sonoluminescence in aqueous solutions. It was shown that the NaCl concentration has multiple effects on the sonochemistry of aqueous solution. For example, they found that the yields of H\textsubscript{2} and H\textsubscript{2}O\textsubscript{2} decreased with increasing NaCl concentration due to the combined physical and chemical effects of ultrasound. Increasing NaCl concentration decreased the solubility of gases and increasing the viscosity of the solution. The combined effects of this leads to the changes in the amount of inertial cavitation bubbles. Thus, the global active bubble
population decreases due to the decreasing gas solubility. On the other hand, under ultrasonication, new radicals such as Na• and Cl• are formed which react with hydroxyl radicals to form new chemical species such as sodium hydroxide (NaOH). In addition, the effect of salt concentration also depends upon the nature of dissolved gases. As an example, under helium (He) atmosphere, the solution is more acidic due to the formation of H+, whereas under Ar atmosphere, the solution is more alkaline i.e., producing NaOH.

In our conditions, the CO₂ conversion experiments were performed under hydrogen atmosphere. H₂ has a different role in CO₂ conversion where it acts as a reducing agent in addition to the hydrogen donor for the Sabatier ratio CO₂:H₂ = 1:4. Hydrogen molecules scavenge the hydroxyl radicals and thus create a reducing environment in the system which is prominent until 1.00 M of the NaCl concentration is used. This phenomenon is clearer from Fig. 9 where the effect of hydrogen concentration and NaCl concentration clearly affects the methane yield. When 2% CO₂ is mixed with 20% H₂, the yield of methane is not affected by the NaCl concentration at all. However, when 2% CO₂ is mixed with 98% H₂, the methane yield increases up to 1.00 M NaCl concentration and then starts decreasing until 5.00 M. At 1.00 M NaCl, an optimal condition exists where there is a balance between the global population of inertial cavitation bubbles and the amount of hydrogen peroxide (H₂O₂) formation by hydroxyl radical recombination. Further increase of the salt concentration has a detrimental effect on the sono-CO₂ conversion where physical effect (increase in viscosity and decrease in gas solubility) is predominant. Under these conditions, the amount of cavitation bubbles is so low that even high concentrations of hydrogen are not enough to overcome this negative effect. Experiments were also performed in synthetic seawater with 2% CO₂ mixed with 20% and 98% H₂ respectively. The salinity of the seawater was 35 g/L (0.60 M). The trend of methane yield in synthetic seawater follows the regular NaCl concentration pattern as seen in Figs. 9 and 10. Although in seawater, there are 10 different chemical compounds present, it appears that the different chemicals do not have any additional effects. This is even clearer from Fig. 10. The yield of all the hydrocarbons gradually increases from pure water to 1.00 M NaCl. The molarity of NaCl in seawater is 0.40 M and the total salt concentration in synthetic seawater is 0.60 M. This might be the reason why seawater gives higher yields than 0.40 M NaCl. In addition, the effect of seawater on the sono-CO₂ conversion process from diluted flue gas (25% flue gas + 75% H₂) was also studied and it is presented in Fig. 11. As expected, the yield of hydrocarbons in seawater increases significantly (40% increase) compared to pure water. This finding indicates that the CO₂ content of the industrial flue gas can be efficiently converted into hydrocarbon fuels by using seawater as ultrasonication media and diluting the gas with H₂.

The gas chromatograms obtained from the GC analysis after 1 h of ultrasonication is presented in Figs. 12 and 13. GC analysis was also

![Gas Chromatogram (GC) of 2% CO₂ + 98% H₂ in 1.00 M NaCl solution.](image-url)
performed every time before the sonication and no hydrocarbons were detected. Fig. 12 shows the gas chromatogram of 2% CO$_2$ + 98% H$_2$ in 1.00 M NaCl solution at 5 °C after 1 h of ultrasonication. The hydrocarbon (CH$_4$, C$_2$H$_4$ and C$_2$H$_6$) peaks are visible in the FID channel whereas the H$_2$, CO and CO$_2$ peaks are visible in the TCD channel. Fig. 13 shows the gas chromatogram of 25% flue gas and 75% H$_2$ in pure water at 5 °C after 1 h of ultrasonication. The N$_2$ gas present in the flue gas is visible in the TCD channel.

4. Mechanisms

The Sabatier process at ambient conditions is a novel process and to the best of our knowledge, this is the only study on the ambient conditions Sabatier process using ultrasound. Therefore, the explicit mechanism(s) of the process is still unknown. However, from our findings and those found by the early works performed by Henglein et al. [24] and Harada et al. [25], we have attempted to provide possible and conceivable mechanisms of the process.

Mechanism 1: Ultrasound induced direct CO$_2$ methanation

The Sabatier reaction is the combination of the reverse water gas shift reaction (Equation (2)) and CO methanation (Equation (3)). The extreme conditions formed during the cavitation bubble collapse can directly decompose or deoxidize CO$_2$ into CO according to the equation (11).

$$\text{CO}_2 \xrightarrow{\text{Ultrasonication}} \text{CO} + \text{O} \tag{12}$$

Then, the carbon monoxide undergoes the methanation process according to reaction (13).

$$3\text{H}_2 + \text{CO} \xrightarrow{\text{Ultrasonication}} \text{CH}_4 + \text{H}_2\text{O} \tag{13}$$

Experiments were also carried out using 2% CO mixed with 98% H$_2$ at 5 °C in order to verify if the CO methanation is possible using ultrasound. The gas chromatogram for CO methanation experiment is presented in Fig. 14 where FID channel shows the peak of methane confirming the formation of methane from CO. A methane yield of 0.4% was observed from 2% CO. Therefore, CO is an intermediate product in CO$_2$ methanation process.

Mechanism 2: Ultrasound induced radical driven CO$_2$ methanation

The H$^\cdot$ produced during ultrasonication (according to equations (8), (9) and (10)) react with CO$_2$ to produce CO according to the equation (14) which then undergoes a series of radical reactions (Reaction 15 - Reaction 20) to produce CH$_4$, C$_2$H$_4$ and C$_2$H$_6$. 

Fig. 13. Gas Chromatogram (GC) of 25% flue gas + 75% H$_2$ in pure water.

Fig. 14. Gas Chromatogram (GC) of 2% CO + 98% H$_2$ in pure water.
In this study, we investigated the possibility to carry out the Sabatier process at ambient conditions in the absence of a catalyst, using power ultrasound only. It was found that when a small quantity of CO₂ (less than 3%) mixed with an inert gas is irradiated by power ultrasound, CO is formed, including a trace amount of methane confirming the occurrence of the Sabatier process. In this process, the reverse water gas shift reactions also occur at ambient conditions. However, when the inert gas is replaced by molecular hydrogen, a drastic improvement is achieved. In the presence of higher hydrogen concentrations, another major reaction called the Fischer-Tropsch process might take place producing higher carbon-number-based hydrocarbons such as C₃H₈ and C₄H₁₀.

Another improvement in the process has been achieved when 1.00 M NaCl or seawater is used as ultrasonicating media instead of pure water. It was found that the salt concentration in this range (0.40 M to 1.00 M) has a beneficial effect in the sonochemistry of gases involving CO₂ and H₂. NaCl tends to reduce the formation of H₂O₂ which is an oxidizing agent. A 1.00 M NaCl solution with a high hydrogen content (98%) in the gas mixture exhibits an excellent synergetic effect by creating a global reducing environment in the system facilitating the CO₂ reduction process through this process. Under these conditions, around 5% total hydrocarbon yield was achieved. In addition to this, we have demonstrated that the CO₂ content from synthetic industrial flue gas can also be converted into valuable hydrocarbons by diluting it using hydrogen. We have shown that, the salt content in the seawater has beneficial effects on the process where around 40% higher hydrocarbon yield was achieved. We have named this novel alternative method for the chemical CO₂ reduction under ultrasound as the “Islam-Pollet-Hihn process” (Fig. 15).

5. Conclusions

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.
