The synthesis of low cost, high efficacy, and durable hydrogen evolution electrocatalysts from the non-noble metal group is a major challenge. Herein, we establish a simple and inexpensive chemical reduction method for producing molybdenum carbide (Mo$_2$C) and tungsten carbide (W$_2$C) nanoparticles that are efficient electrocatalysts in alkali and acid electrolytes for hydrogen evolution reactions (HER). Mo$_2$C exhibits outstanding electrocatalytic behavior with an overpotential of $-134$ mV in acid medium and of $-116$ mV in alkaline medium, while W$_2$C nanoparticles require an overpotential of $-173$ mV in acidic medium and $-130$ mV in alkaline medium to attain a current density of 10 mA cm$^{-2}$. The observed results prove the capability of high- and low-pH active electrocatalysts of Mo$_2$C and W$_2$C nanoparticles to be efficient systems for hydrogen production through HER water electrolysis.

Keywords: Mo$_2$C, W$_2$C, nanoparticle, HER, electrocatalyst

INTRODUCTION

A direct and effective route to clean and renewable hydrogen (H$_2$) production by water splitting requires a robust catalyst to ensure sustainable efficiency (Vikraman et al., 2017). Platinum (Pt)-based systems are recognized as highly energetic HER catalysts that boast various pH tolerances and almost zero overpotential, but their high cost, originating from the scarcity of platinum, severely hinders their extensive use (Jacobsson et al., 2013; Peng et al., 2014). To reduce the use of Pt, intensive research has been conducted to prepare low-cost, highly active, and electrochemically stable HER electrocatalysts comprised of abundant elements as an alternative (Vikraman et al., 2018; Hussain et al., 2019a). Numerous types of non-scarce transition metal compounds, such as layered transition metal dichalcogenides (LTMDs) (Laursen et al., 2012; Seok et al., 2017; Hussain et al., 2018), phosphides (Lv and Wang, 2017; Pei et al., 2018), transition metal carbides (TMC) (Huang et al., 2016; Shi et al., 2017), and their composites (Ren et al., 2018; Vikraman et al., 2019b) have been shown to produce excellent HER activities because of their unique electronic structures.

Various molybdenum selenide (MoSe$_2$)-based materials, in particular, have been reported as being...
suited for replacing Pt in HER electrocatalysts (Ren et al., 2018; Hussain et al., 2019a; Vikraman et al., 2019a). In addition, attaching Mo2C and W2C to a carbon matrix has been shown to produce high-rate charge transfer properties during HER and to alleviate surface aggregation (Pan et al., 2014; Youn et al., 2014; Wu et al., 2016). Previous reports suggested that the HER electrocatalytic performance of Mo2C- and W2C-based catalysts mainly results from the morphology (Ang et al., 2016; Ishii et al., 2016; Peng et al., 2017), crystalline phases (Wan et al., 2014; Lin et al., 2017), and composition (Yu et al., 2018; Zhang et al., 2018) of the catalysts and the synthetic protocol. However, the critical challenge is to design and develop carbide-based catalysts with comparable catalytic performance to Pt for practical applications. Until now, carbide-based materials have shown inferior catalytic properties due to their poor activities (Wu et al., 2016; Yu et al., 2018; Zhang et al., 2018). An earlier study reported the HER behavior of commercially available Mo2C meshes in both basic and acidic solutions, showing a comparatively high overpotential of $-190~\sim~-230$ mV at a cathodic current of 10 mA cm$^{-2}$ (Vrubel and Hu, 2012). Performance has since been upgraded by tuning its nanocrystal size (Ma R. et al., 2015; Chen et al., 2016). Hence, Mo2C and W2C nanoparticles with high catalytic activity and robustness remain open for future research.

Various methods have been employed to prepare TMC-based catalysts (Wu et al., 2016; Zhu et al., 2016; An and Xu, 2019). Gong et al. obtained WC/ MoC-based electrocatalysts by carbonizing W/O3 or Mo/O3 under the flow of carbon precursors (C2H6, CH4, or CO, and H2), but very low surface areas were obtained (Gong et al., 2016). Tantalum carbide nanocrystals have been prepared via a refined Cl2-assisted "micro-cutting-fragmentation" approach and produced an overpotential of $\sim-146$ mV@10 mA cm$^{-2}$ for HER (Kou et al., 2017). Different methodologies have been used to prepare Mo2C and its hybrids for HER applications (Pu et al., 2016; Kou et al., 2018; Liang et al., 2019). Tungsten carbides can exist in different phases, such as WC, metastable W2C, and WC1-x, but during the last decade, most researchers have exclusively focused on the WC phase instead of the W2C phase (Neylon et al., 1999; Ishii et al., 2016). W2C/HC synthesized by Kou et al. (2019) showed an overpotential of 159 mV@10 mA cm$^{-2}$. As per experimental and theoretical calculations, the W2C phase exhibits more HER active catalytic properties than does WC, with a low negative Gibbs free energy ($\Delta$G) for hydrogen adsorption and high Fermi level electronic density of states (DOS) (Colton et al., 1975; Gong et al., 2016). $\beta$-phase Mo2C and the W2C phase, in particular, have been validated as effective HER electrocatalysts despite their bulky natures, and their activity could be further increased by engineering with appropriate nanosize structures (Huang et al., 2016).

Herein, we have successfully synthesized Mo2C and W2C nanoparticles for HER application via a simple and economical chemical reduction method. The electrochemical results indicate that Mo2C nanoparticles exhibit superior HER electrocatalytic behavior over W2C in both alkaline and acid solutions, with small Tafel slopes and distinct solubility. We believe that our present investigation provides effective strategies for designing and preparing the new nanostructured TMC-based HER catalysts.

**RESULTS AND DISCUSSION**

The chemically reduced synthesis scheme and the atomic structures of the Mo2C and W2C nanoparticles are pictorially represented in Figure 1. Raman characterization was performed for structural confirmation of commercial and chemically reduced Mo2C and W2C nanoparticles. Figure 2A shows the Raman spectra of commercial Mo2C and W2C and chemically reduced Mo2C and W2C. The commercial Mo2C revealed unclear peaks, whereas the chemically reduced Mo2C produced distinctive peaks at 661, 818, and 990 cm$^{-1}$, credited to $\beta$-Mo2C (Hussain et al., 2019b). In addition, the G band was positioned at 1,582 cm$^{-1}$ and the D band was positioned at 1,349 cm$^{-1}$, which corresponds to the sp2-bonded carbon atoms and disarranged graphite carbon, respectively (Ma F. et al., 2015). The intensity ratio of the D-band to the G-band (i.e., $I_D/I_G$) is 0.85 for Mo2C, comparable to long-time carbonized graphene layers with high conductivity, which may facilitate charge transfer during HER (Li et al., 2016; Lv et al., 2017; Wang et al., 2017). For commercial and chemically reduced W2C, the strong peaks observed at 693 and 807 cm$^{-1}$ originate from the stretching vibration of W-C (Yan et al., 2017). The D and G bands were exhibited at 1,351 and 1,583 cm$^{-1}$ for the chemically reduced W2C (Yan et al., 2017; Zhang et al., 2018). The observed results are in good agreement with previous reports (Yan et al., 2017; Hussain et al., 2019a).

X-ray diffraction (XRD) was investigated to reveal the material structure of the commercial and chemical Mo2C and W2C nanoparticles (Figure 2B). For Mo2C, the XRD patterns revealed reflections at 34.5, 38.1, 39.5, 52.3, 61.7, 69.6, 74.7, and 75.7, which were indexed to the (100), (002), (101), (102), (110), (103), (112), and (201) planes of $\beta$-Mo2C (JCPDS: 35-0787), which is the most active phase of Mo2C for HER. In the case of W2C, the XRD patterns produced peaks at 31.5, 35.1, 48.8, 64.1, 65.8, 73.2, 75.6, and 77.1° due to the (020), (002), (220), (041), (123), (004), (142), and (322) lattice planes, respectively (JCPDS: 89-2371). Compared with commercial samples, the chemically reduced samples showed higher-intensity peaks, which can be attributed to the enriched crystallinity in the nanoparticles compared to in bulk (Hussain et al., 2019a). No discernible peaks in either the Mo2C or W2C samples could be assigned to Mo/W, carbide, or other Mo/W non-stoichiometric phases and impurities, indicating the capability of the synthetic method to prepare effective nanostructures from bulk.

Morphology and microstructure modifications were inspected using field emission scanning electron microscopy (FESEM) and transmission electron microscopy (TEM). Figures 3a–c show FESEM images for reduced Mo2C nanoparticles. The observed images clearly indicated that larger sized grains were constructed through the accumulation of spherically shaped nanoparticles. The composition of reduced Mo2C nanoparticles was examined by energy dispersive spectroscopy (EDS), as shown in Figure S1. The observed composition of the chemically reduced sample is in good agreement with the claim of Mo2C formation, and EDS mapping images for the nanoparticles are provided in Figure S2. TEM images at different magnifications of Mo2C nanoparticles are provided in Figures 3d–g. The large grains are clearly seen in the lower-magnification TEM image (Figure 3d), and the typical
2D layered structures are shown in the higher-magnification images. A high-resolution TEM image showing a fingerprint-like structure is shown in Figure 3g, and its fast Fourier transform (FFT) and inverse FFTs are inserted. The intensity profile extracted proved the existence of (101) lattice plane spacing (0.228 nm) between the fringes, as shown in Figure 3h.
Hence, the microscopic images clearly proved the formation of Mo$_2$C nanoparticles.

Figure 4 shows FESEM and TEM images of chemically reduced W$_2$C nanoparticles. The nanoparticles consist of inhomogeneous grains (Figures 4a–c). The EDS spectrum confirmed the existence of W$_2$C nanoparticles (Figure S3), and their mapping images further supported the claim of W$_2$C nanoparticle formation (Figure S4). The TEM images provided valuable insights regarding the W$_2$C nanoparticles (Figures 4d–g). The irregularly sized nanograins were clearly seen in the low- and higher-magnification TEM images (Figures 4f,g). The FFT image showed the (002) W$_2$C plane (0.26 nm spacing) (Figure 4h). The observed results are well-correlated with the XRD results.

An X-ray photoelectron spectroscopy (XPS) study was conducted to validate the composition of reduced Mo$_2$C and W$_2$C. The XPS survey spectra revealed the occurrence of Mo$_2$C (C and Mo)- and W$_2$C (C and W)-based elements, as shown in Figures S5A,B. Figure 5A shows the de-convoluted high-resolution region for Mo 3d, with the Mo 3d$_{5/2}$ and Mo 3d$_{3/2}$ peaks at 228.6 and 231.9 eV, which reveals the carbidic Mo phase. The peaks at 233.3 and 235.9 eV are from molybdenum oxide (Mo$_6^{6+}$), indicating surface oxidation in an air environment (Cui et al., 2014; Tang et al., 2015; Huang et al., 2016; Fan et al., 2018; Hussain et al., 2019a). The C 1s spectrum (Figure 5B) at a 284.8 eV binding energy is characteristic of the sp$^2$ carbon relation in Mo$_2$C, whereas a satellite peak emerges at 288.8 eV due to C–O bonding (Wu et al., 2016). Figure 5C shows the high-resolution W 4f XPS spectrum from chemically reduced W$_2$C. The deconvoluted peaks revealed at 31.64 and 33.81 eV were credited to 4f$_{7/2}$ and 4f$_{5/2}$, respectively, for the W 4f atom. The high-resolution C 1s spectrum (Figure 5D) of W$_2$C exposed the sp$^2$ graphitic carbon peak at 283.02 eV and C=O...
peak at 285.1 eV (Berglund et al., 2014; Ko et al., 2017). The observed results confirmed the formation of Mo$_2$C and W$_2$C, which is in good agreement with the earlier literature (Ma F. et al., 2015; Yan et al., 2017). The surface area modifications were measured by the nitrogen (N$_2$) adsorption/desorption isotherms for chemically reduced Mo$_2$C and W$_2$C nanoparticles via the Brunauer Emmett Teller (BET) method (Figures S6A,B). Surface area of 0.91 and 1.75 m$^2$g$^{-1}$ were observed for the chemically reduced Mo$_2$C and W$_2$C, respectively, compared with the reported values of their commercial samples (Gao et al., 2014; Hussain et al., 2019a). In addition, the pore diameter vs. pore volume profile (Figure S6B) shows the mesoporous nature of chemically reduced Mo$_2$C and W$_2$C, with pore diameters of 14.9 and 21.4 nm and pore volumes of 0.003 and 0.009 cm$^3$g$^{-1}$, respectively.

The HER electrocatalytic activities of Mo$_2$C- and W$_2$C-coated nickel foam (NF) electrodes were analyzed by linear sweep voltammogram (LSV) in 1 M KOH and 0.5 M H$_2$SO$_4$ electrolyte solutions (scan rate of 10 mV s$^{-1}$, three-electrode setup). For the evaluation, a commercial Pt/C was used as an electrode, and the results were as follows. Figure 6A shows the LSV curves of commercial Pt/C and reduced Mo$_2$C and W$_2$C catalysts in a 0.5 M H$_2$SO$_4$ solution. As anticipated, the commercial Pt/C catalyst showed the highest HER activity, which had an overpotential of ∼49 mV. For bare NF, Mo$_2$C, and W$_2$C, overpotentials of −423, −134, and −170 mV were needed to achieve 10 mAcm$^{-2}$ in acidic electrolyte, respectively, lower than those of the commercial samples (Vrubel and Hu, 2012; Chen et al., 2013). The overpotentials of the chemically reduced Mo$_2$C and W$_2$C were much closer to the recently reported values for carbide-based materials in acid medium, such as Mo$_2$C encapsulated by nitrogen and phosphorus codoped carbon shells ($\eta_{10\text{mA/cm}^2}$@-260 mV) (Li et al., 2016), Mo$_2$C nanoparticles embedded in chain-like Ketjenblack carbon ($\eta_{10\text{mA/cm}^2}$@-221 ∼263 mV) (Wang et al., 2017), porous MoC$_x$ nano octahedrons ($\eta_{10\text{mA/cm}^2}$@-142 mV) (Wu...
et al., 2015), 3D porous scaffold-like Mo\textsubscript{2}C/C nanosheet hybrids (η\textsubscript{10mA/cm\textsuperscript{2}}=233 mV) (Wang et al., 2018), reduced graphene oxide-based Mo\textsubscript{2}C composites (η\textsubscript{10mA/cm\textsuperscript{2}}=206 mV) (Ojha et al., 2016), Mo\textsubscript{2}C nanoparticle-decorated graphitic carbon sheets (η\textsubscript{10mA/cm\textsuperscript{2}}=200–210 mV) (Cui et al., 2014), Mo\textsubscript{2}C particles embedded in a sulfur and nitrogen codoped mesoporous carbon matrix (η\textsubscript{10mA/cm\textsuperscript{2}}=146 mV) (An et al., 2017), and Mo\textsubscript{2}C NCs on vertically aligned graphene (η\textsubscript{10mA/cm\textsuperscript{2}}=152 mV) (Fan et al., 2017). The electrocatalytic properties of Pt/C, Mo\textsubscript{2}C, and W\textsubscript{2}C catalysts were appraised in a 1 M KOH medium (Figure 6B). Similarly, the Pt/C, Mo\textsubscript{2}C, and W\textsubscript{2}C electrocatalysts produced −48, −116, and −130 mV overpotentials to drive the 10 mA cm\textsuperscript{−2} reaction in an alkaline electrolyte. The bare NF did not produce viable HER properties in a 1 M KOH medium.

The Tafel slope signifies the characteristic activity acquired of an electrocatalyst and is derived using the Tafel equation for the HER. As shown in Figures 6C,D, Pt/C offers Tafel slopes of 43 and 48 mV dec\textsuperscript{−1} for acidic and alkaline electrolytes, respectively, which is comparable with the reported results (Fan et al., 2018). The extracted slope values from the Tafel plots were 83 and 86 mV dec\textsuperscript{−1} for the acidic and 65 and 100 mV dec\textsuperscript{−1} for the alkaline for reduced Mo\textsubscript{2}C and W\textsubscript{2}C, respectively. These values indicate that the Volmer-Heyrovsky reaction step is obeyed for the whole HER process (Bockris and Potter, 1952; Yuan et al., 2018). Another important parameter, the exchange current density (j\textsubscript{0}), was extracted to evaluate HER activity by extrapolating the linear region of the Tafel plot. A chemically reduced Mo\textsubscript{2}C catalyst displays j\textsubscript{0} values of 0.846 and 0.131 mA cm\textsuperscript{−2} in alkali and acidic media, respectively, while a chemically reduced W\textsubscript{2}C catalyst shows j\textsubscript{0} values of 0.438 and 0.194 mA cm\textsuperscript{−2}. The observed parameters are provided in Table 1. A detailed comparison of chemically reduced Mo\textsubscript{2}C and W\textsubscript{2}C HER parameters, with the reported carbide-based materials in alkaline and acidic media, are provided in Tables S1, S2, respectively.

The observed HER properties are credited to the reduced sizes of Mo\textsubscript{2}C and W\textsubscript{2}C nanostructures and their improved morphological properties in terms of edge sites. High electrical conductivity allows for rapid ion/electron transfer between the active electrocatalyst edge sites and also provides a high interaction area between the electrolyte and the electrode, which in turn enhances the electrochemical performance. The charge transport mechanism was clarified by employing electrochemical impedance spectroscopy (EIS) studies to understand the HER mechanism of Mo\textsubscript{2}C and W\textsubscript{2}C nanoparticles at the interface between electrodes and electrolytes. The charge transfer properties with resistance (R\textsubscript{ct}) are exhibited for Pt/C in acidic and alkaline media as shown in Figures S7A,B. The lower R\textsubscript{ct} values for chemically reduced Mo\textsubscript{2}C and W\textsubscript{2}C in acidic and alkaline media confirmed that they favor rapid electron transport in H\textsubscript{2} evolution (Figures S7A,B).
We estimated the electrochemically active surface area (ECSA) through cyclic voltammetry (CV), which was accomplished at different scan rates from 10 to 100 mVs$^{-1}$ in the non-Faradaic regions for Mo$_2$C and W$_2$C, as shown in Figures S8A–D, respectively (Zhou et al., 2016; Hussain et al., 2019a; Vikraman et al., 2019a). The double-layer capacitance ($C_{dl}$) was extracted from the fitted slope value of the current differences ($\Delta j_a - \Delta j_c$) of the cathodic and anodic peaks of CV profiles at 0.24 V vs. RHE (Figure S8E). The extracted $C_{dl}$ values were 2.13 and 1.42 mF.cm$^{-2}$ in acid medium and 2.90 and 1.86 mF.cm$^{-2}$ in alkaline medium for Mo$_2$C and W$_2$C, respectively. The ECSA values were assessed through a previously described procedure (Vikraman et al., 2019a) and were 60.8 and 40.6 cm$^2$ in an acidic and 72.5 and 46.5 cm$^2$ in a alkaline medium for Mo$_2$C and W$_2$C, respectively, indicating higher HER activity for the Mo$_2$C system. We estimated the amount of surface active sites using the method reported by Fei et al. (2015). The turnover frequency (TOF) values of Mo$_2$C and W$_2$C were calculated in the acidic and alkaline media. The TOF values of Mo$_2$C are 0.005 and 0.037 H$_2$.s$^{-1}$ at overpotentials of $-134$ and $-116$ mV, and those of W$_2$C are 0.015 and 0.034 H$_2$.s$^{-1}$ at overpotentials of $-173$ and $-130$ mV in acidic and alkaline media, respectively. The observed TOF values are comparable with previous reports (Chen et al., 2011; Fei et al., 2015; Ma L. et al., 2015; Zhang et al., 2017).

The robustness of the Mo$_2$C and W$_2$C catalysts was analyzed by carrying out chronoamperometric performances in 0.5 M H$_2$SO$_4$ and in 1 M KOH for 20 h; the results are shown in

**TABLE 1** | Comparison of the electrochemical parameters of different electrocatalysts.

| Electrolyte | Electrocatals | Tafel slope (mV·dec$^{-1}$) | Overpotential (mV vs. RHE) @ 10 mA·cm$^{-2}$ | Exchange current density ($j_0$, mA·cm$^{-2}$) |
|-------------|---------------|-------------------------------|---------------------------------------------|---------------------------------------------|
| 0.5 M H$_2$SO$_4$ | Pt/C | 43 | $-49$ | 1.03 |
| Mo$_2$C | 83 | $-134$ | 0.131 |
| W$_2$C | 86 | $-173$ | 0.194 |
| Bare NF | 168 | $-423$ | 0.022 |
| 1 M KOH | Pt/C | 48 | $-48$ | 0.891 |
| Mo$_2$C | 65 | $-116$ | 0.846 |
| W$_2$C | 100 | $-130$ | 0.438 |
| Bare NF | $-$ | $-$ | $-$ |

**FIGURE 6** | HER performance of bare NF, Pt/C, Mo$_2$C, and W$_2$C nanoparticle-decorated NF. (A,C) LSV profiles and their Tafel plots in 0.5 M H$_2$SO$_4$ and (B,D) LSV profiles and their Tafel plots in 1.0 M KOH.
**FIGURE 7** | Long-term stability tests (A,B) chronoamperometric curves for Mo$_2$C- and W$_2$C-loaded NF electrocatalyst in 0.5 M H$_2$SO$_4$ (inset: corresponding LSV profiles for initial and after 20 h of HER performance) and (C,D) Chronoamperometric curves for Mo$_2$C- and W$_2$C-loaded NF electrocatalyst in 1.0 M KOH (inset: corresponding LSV profiles for initial and after 20 h of HER performance).

**Figures 7A–D.** The LSV profiles of Mo$_2$C and W$_2$C catalysts were examined after 20 h of HER operation (−0.6 to 0.15 V vs. RHE at a scan rate of 10 mV s$^{-1}$) in alkaline and acid media (Figure 7). The polarization curves revealed the robust nature of Mo$_2$C after 20 h of working operation, whereas W$_2$C showed slight degradation. Hence, the observed deliverables established the capability of chemically reduced Mo$_2$C catalysts with long-term durability in alkaline and acidic media, which makes them interchangeable for high-cost materials.

Furthermore, the stability of the Mo$_2$C and W$_2$C catalysts was investigated by XPS and FESEM analysis after continuous 20 h-HER operation in electrolytic solution (acidic medium); the results are shown in Figures S9, S10. The observed results also confirm no dramatic changes in XPS and FESEM data after continuous 20 h HER operation.

**CONCLUSIONS**

Chemically reduced Mo$_2$C and W$_2$C produced using an economical reduction method were successfully employed as electrocatalysts for application in HER. The observed HER results revealed that Mo$_2$C and W$_2$C nanoparticles had low overpotentials ($\eta_{10\text{mAcm}^{-2}} = -134$ and $-116$ mV and $-173$ and $-130$ mV for Mo$_2$C and W$_2$C nanoparticles, respectively) with small Tafel slopes (83 and 65 mV.dec$^{-1}$ and 86 and 100 mV.dec$^{-1}$ for Mo$_2$C and W$_2$C nanoparticles, respectively) in a 0.5 M H$_2$SO$_4$ and in 1 M KOH electrolyte media. Both carbide catalysts showed strong stability in the alkaline and acidic media for over 20 h of operation. Thus, this work shows a viable way to synthesize nanostructured TMC-based electrocatalysts for hydrogen production.

**EXPERIMENTAL SECTION**

**Materials and Methods**

The commercial Mo$_2$C and W$_2$C chemicals of reagent grade were acquired from Sigma-Aldrich and were used without further purification. The following procedure was followed to prepare the chemically reduced Mo$_2$C and W$_2$C nanostructures (Hussain et al., 2019a). First, 2 g of commercial powder was well-disseminated in 100 mL of ethanol in a beaker to form a clear solution with the assistance of a room temperature stirring process. Subsequently, 50 mL of liquid ammonia solution was mixed with the black solution mixture, which was followed by a magnetic stirring at 85°C until the ethanol was completely evaporated from the mixture. The settled residue was then purified with de-ionized water and alcohol, sometimes using a centrifuge process, and the resultant material was placed in an
oven at 60°C for 6 h. Finally, the collected black powders were placed in a quartz tube, and their temperature was raised with a heating rate of 5°C/min to attain 850°C with the support of a CH4/Ar/H2-mixture gas flow (50 sccm). The final chemically reduced Mo2C and W2C samples were kept in a vacuum desiccator for further analysis.

**Electrochemical Measurements**

The electrocatalytic HER properties were examined in an acid medium (0.5 M H2SO4 solution) and an alkaline medium (1 M KOH) by using a typical three-electrode setup. A saturated calomel electrode (SCE) and a carbon rod were used as the reference and counter electrodes, respectively. For the preparation of a working electrode, a 10:80:10 weight ratio of poly (vinylidene fluoride), active materials (W2C and Mo2C), and carbon black was used with an N-methyl-2-pyrrolidone solvent. The resultant sample was coated onto NF and dried overnight at 90°C. Mo2C- and W2C-loaded NF was employed as the working electrode. The LSV was recorded using a scan rate of 10 mV s⁻¹ at room temperature. All the LSV performances were completed using SCE and then referenced to a reversible hydrogen electrode (RHE) scale using the following equation: E (RHE) = E (SCE) + E° (SCE) + 0.059 pH. An electrochemical impedance spectroscopy (EIS) study was performed within the 0.1 Hz to 1 MHz frequency with a perturbation voltage of 10 mV.

**Characterization**

Mo2C and W2C nanoparticles were studied using Raman spectroscopy (Renishaw Invia RE04, Ar laser—512 nm), FE-SEM (HITACHI S-4700), a Rigaku Ultima IV diffractometer with Cu-Kα radiation (0.154 nm), JEOL-2010F TEM with the help of Gatan DM software (version 3.0), PHI 5000 Versa Probe XPS, and a 3Flex surface characterization analyzer for nitrogen adsorption and desorption measurement at 77 K (Micromeritics, USA).

**DATA AVAILABILITY STATEMENT**

All datasets generated for this study are included in the article/Supplementary Material.

**AUTHOR CONTRIBUTIONS**

SH and JJ prepared the manuscript. SH performed the material synthesis. DV and AF actively took part in the characterization of catalysts. WS and K-SA performed XPS measurement and physical characterization of synthesized materials. H-SK, S-HC, and JJ did planning, design experimental work, and discussion. JJ edited the paper.

**FUNDING**

This research was supported by the Basic Science Research Program through the National Research Foundation of Korea (NRF), funded by the Ministry of Education (2015M3A7B7045194, 2017R1C1B5076952, and 2016M3A7B4909942), by the MOTIE (10052928) and the KSRC (Korea Semiconductor Research Consortium) support programs for the development of future semiconductor devices. This work was supported by the Korea Institute of Energy Technology Evaluation and Planning (KETEP) and the Ministry of Trade, Industry & Energy (MOTIE) of the Republic of Korea (20172010106080).

**SUPPLEMENTARY MATERIAL**
