Supporting Information

ABSTRACT: The new biomimetic ligands N4Py2Ph2 (1) and N4Py2Ph2amide (2) were synthesized and yield the iron(II) complexes [FeII(N4Py2Ph2)(NCCH3)](BF4)2 (3) and [FeII(N4Py2Ph2amide)](BF4)2 (5). Controlled orientation of the Ph substituents in 3 leads to facile triplet spin reactivity for a putative FeIV(O) intermediate, resulting in rapid aren hydroxylation. Addition of a peripheral amide substituent within hydrogen-bond distance of the iron first coordination sphere leads to stabilization of a high-spin FeIII-OOR species which decays without aren hydroxylation. These results provide new insights regarding the impact of second-coordination sphere effects at nonheme iron centers.

Nonheme iron oxygenases are potent and selective catalysts, typically operating through iron-peroxo (FeOO(H/R)) and iron-oxo (FeO) intermediates. For example, aren hydroxylation is mediated by a class of mammalian nonheme iron enzymes known as aromatic amino acid hydroxylases (e.g., Tyr, Phe, and Trp hydroxylases), mammalian nonheme iron enzymes known as aromatic amino acid hydroxylases (e.g., Tyr, Phe, and Trp hydroxylases), and both FeII-OOR and FeIII(O) species are postulated as key intermediates in their catalytic cycles. Much effort has gone into the preparation of synthetic analogs of FeOO(H/R) and FeIV(O) intermediates, employing ligands designed to stabilize these species through the use of oxidatively inert, biologically relevant donor groups and steric shielding of the metal center. Enzymes, however, also have at their disposal the ability to control the second coordination sphere through the juxtaposition of substrates at appropriate distances from the metal center and through interacting residues that can tune reactivity via hydrogen bonds. In contrast, model complexes that are designed to incorporate these second-coordination sphere effects are less developed.

Herein we report the synthesis of two new polydentate ligands, N4Py2Ph2 (1) and N4Py2Ph2amide (2) (N4Py = N,N-bis(2-pyridylmethyl)-N-bis(2-pyridyl) methylamine) (Figure 1), which have been designed to examine second-coordination sphere effects in nonheme Fe model complexes. The new ligand 1 incorporates phenyl substituents as constrained substrates for oxidation, while 2 includes an additional amide group as a hydrogen-bond donor for interaction with metal–oxygen intermediates. An iron(II) complex from 1 undergoes rapid, regioselective aren hydroxylation at one Ph ring, and a novel reaction channel appears accessible by the positioning of the phenyl ring in the second coordination sphere. In contrast, the FeII complex from 2 does not undergo aren hydroxylation but rather leads to the formation of a metastable FeIII-OOR complex. The latter result suggests a significant influence of the amide-derived H-bond donor group on the stability of the FeIII-OOR species. Computational studies, in combination with the experimental data, provide key insights regarding the importance of the second-coordination sphere effects introduced by 1 and 2.

A key step in the synthesis of diphenyl-substituted 1 was a Suzuki–Miyaura coupling between bis(6-bromo-2-pyridyl) ketone and C6H5B(OH)2, with the final ligand 1 prepared as in Figure S1. Stirring of 1 equiv of Fe(BF4)2 and 1 in CH2CN (Scheme 1) leads to X-ray quality crystals of [FeII(N4Py2Ph-NCCH3)](BF4)2 (3) (92%) from Et2O/CH2CN. X-ray

diffraction reveals the structure of 3 as shown in Figure 2, which has a six-coordinate Fe(II) center bound to the pentadentate N4Py2Ph ligand and one CH3CN molecule. The Fe-N distances for 3 (2.165(1)–2.379(1); 2.172(1)–2.442(1) Å) are indicative of high-spin (hs) Fe(II)–N(py) bond lengths. The paramagnetically shifted $^1$H NMR spectrum (from 151 to $-7$ ppm) as well as a magnetic moment measurement by Evan’s method in CD3CN (exptl $\mu_{\text{eff}}$ = 5.2; calcld (spin-only, $S$ = 2) $\mu_{\text{eff}}$ = 4.9) confirmed that 3 is hs-Fe(II). Thus the addition of phenyl substituents to the N4Py scaffold causes a spin state change from low-spin (ls) Fe(II) for [Fe(II)(N4Py(CH3CN)]2+ to hs-Fe(II) for 3.

Addition of a small excess (4–5 equiv) of 'BuOOH to 3 in CH3CN at room temperature results in an immediate color change from yellow to green and a new UV–vis band ($\lambda_{\text{max}}$ = 758 nm, $\epsilon$ = 1880 M$^{-1}$ cm$^{-1}$) (Figure 3). Characterization by LDI-MS(+) revealed a parent ion at m/z 590.167, consistent with ligand mono-oxidation. The product N4Py2PhOH was isolated in 65% yield following purification.

The [Fe(III)(N4Py,PPh)](BF4)$_2$ (4) from 'PrO/CH3CN (Figure 2). The structure confirmed that arene hydroxylation had occurred to give a phenolato-iron(III) complex. The Fe-N bond lengths (1.9193(15)–2.0358(15) Å) and EPR spectrum (g 2.39, 2.12, 1.90) indicate 4 is an Fe(III) complex.

The reaction of 3 with 'BuOOH, PhIO or IBX-ester results in a regioselective intramolecular arene hydroxylation to give a single ortho-hydroxylated product. This selectivity for the same product points to a common metal-based intermediate for all three oxidants, most likely the proposed [FeIV(O)(N4Py2Ph)]2+ species (Scheme 2). Further support for the involvement of [FeIV(O)(N4Py2Ph)]2+ comes from UV–vis and NMR spectral titrations, where maximal formation of 4 is clearly seen following the addition of 1 equiv of IBX-ester (Figures S9, S10). These data are consistent with two-electron OAT from IBX-ester to 3 to give an Fe(IV)(O) species that then hydroxylates the phenyl ring. Reaction of PhI with O acts to 18O incorporation (88%) in 4 as seen by LDIMS-MS (Figure S16), indicating that the O atom in 4 is derived exclusively from the organic oxidant, and providing additional evidence for the Fe(IV) species as a key intermediate.

Attempts were made to trap the Fe(IV) intermediate derived from 3. Reaction of 3 with IBX-ester and 'BuOOH was examined at low temperature but led only to the slow formation of 4 (nearly 100% in CH3CN, Figure S11) or decomposition (nearly 60% in CH3Cl, Figure S11), suggesting that the Fe(IV) species rapidly reacts with the C6H$_5$H$_2$ substituent even at low temperature. In contrast, the stable [FeIV(O)(N4Py)]2+ does not react with C6H$_5$H$_2$ (500 equiv) even over prolonged reaction times (>14 h). Thus [FeIV(O)(N4Py)]2+ is not competent to mediate benzene hydroxylation.

A few examples of aromatic hydroxylation mediated by nonheme Fe complexes are known, and some have implicated the importance of orienting the aromatic substrate near the metal. However, the mechanism of hydroxylation and identity of the active oxidant in these systems remain poorly understood. In the case of 3, rapid intramolecular phenol hydroxylation is observed, but there is a complete lack of reactivity between [FeIV(O)(N4Py)]2+ and C6H$_5$. Similar contradictory observations have been discussed for intra- vs intermolecular phenol hydroxylation in the Fe(III)-TPA (TPA = tris(2-pyridylmethyl)amine) system, but no explanation has been given.4a,b,8c To gain insight into the mechanism of intra- vs intermolecular arene hydroxylation, we performed density functional theory (DFT) calculations on [FeIV(O)(N4Py)]2+ and compared the results with those previously obtained for [FeIV(O)(N4Py)]2+ and C6H$_5$.

The [FeIV(O)(N4Py2Ph)]2+ structure has close lying triplet and quintet spin configurations, with a favorable triplet spin state in the gas phase and almost degenerate spin states at free energy level at 298 K. This spin state splitting is much smaller than that found for [FeIV(O)(N4Py)]2+, where the triplet spin state was found to be at least 8 kcal mol$^{-1}$ more stable than the
quintet. Electrophilic attack of the oxo group on the ortho-carbon atom leads to electron transfer from Ph to the \( \pi^*_{xz} \) orbital in the triplet spin state (\( \pi \)-pathway), whereas in the quintet state the virtual \( \sigma^*_{xz} \) (\( \sigma \)-pathway) or \( \pi^*_{yz} \) (\( \pi \)-pathway) are the possible acceptor orbitals. The \( \pi \)-pathway generates an intermediate with configuration \( \pi_{yz}^* \pi_{yz} \pi_{yz} \pi_{yz} \pi_{yz}^* \pi_{yz}^* \pi_{yz}^* \pi_{yz}^* \phi_{1s}^* \), while the \( \sigma \)-channel gives \( \pi_{yz}^* \pi_{yz} \pi_{yz} \pi_{yz} \pi_{yz}^* \pi_{yz}^* \sigma_{1s} \sigma_{1s} \phi_{1s}^* \), and the \( \pi \)-pathway gives \( \pi_{yz}^* \pi_{yz} \pi_{yz} \pi_{yz} \pi_{yz}^* \pi_{yz}^* \sigma_{1s} \sigma_{1s}^* \phi_{1s}^* \).

As seen in Figure 4, the gas-phase energies predict that the \( \pi \) channel is the lowest in energy, although the quintet transition states are not that far above \( ^3TS_c \). The \( \sigma \)-pathway is slightly favored over the \( \pi \)-pathway at the free-energy level. These results differ dramatically from calculations on \([\text{Fe}^{III}(\text{O})(\text{N}4\text{Py})]^2+\), which show that the \( \pi \)-pathway is highly destabilized compared to the \( \sigma \)-pathway (\( \Delta \Delta G^0 > 15 \text{ kcal/mol} \)).

Much effort has gone into determining the factors that control the reactivity of \( \text{Fe}^{IV}(\text{O}) \) species. For both nonheme iron models and enzymes, the triplet (low-spin) state for \( \text{Fe}^{IV}(\text{O}) \) is described as generally unreactive, whereas quintet (high-spin) \( \text{Fe}^{IV}(\text{O}) \) is considered a powerful oxidant. The high reactivity for the quintet species has been attributed to the accessibility of the \( \sigma \)-reaction channel, with an approximate collinear approach (Fe–O–C(or H) = 180°) of the substrate donor orbital with the Fe=O unit. The triplet \( \text{Fe}^{IV}(\text{O}) \), on the other hand, is limited to the \( \pi \)-reaction channel with an approximate perpendicular approach for overlap with the \( \pi^*_{yz/fe} \) orbital. The ligands in the equatorial plane of triplet \( \text{Fe}^{IV}(\text{O}) \) complexes typically provide a steric barrier to this channel and make it prohibitively high in energy, and a low-lying quintet excited state is often invoked to explain the observed reactivity for triplet \( \text{Fe}^{IV}(\text{O}) \).

The DFT calculations for \([\text{Fe}^{IV}(\text{O})(\text{N}4\text{Py})]^2+\) indicate that the low-spin, \( \pi \)-pathway becomes a viable reaction channel by positioning the phenyl substrate in the second coordination sphere. In comparison, triplet \([\text{Fe}^{IV}(\text{O})(\text{N}4\text{Py})]^2+\) is completely unreactive toward \( \text{C}_9\text{H}_8 \) consistent with the fact that the \( \pi \)-pathway is sterically blocked. Computational investigations have asserted the importance of substrate positioning (\( \sigma \) vs \( \pi \)) in controlling nonheme Fe(O) reactivity, but to our knowledge the results herein provide the first combined experimental/theoretical evidence for the importance of \( \sigma \) vs \( \pi \) substrate orientation in a synthetic nonheme iron system.

Addition of another secondary coordination sphere element, in the form of a potential H-bond donor group, dramatically changes the reactivity of the nonheme \( \text{Fe}^{III} \) complex. The complex \([\text{Fe}^{III}(\text{N}4\text{Py})_{2}\text{Ph,amide}^+][\text{BF}_4]^2 \) (5) was readily prepared from 2, and an X-ray structure reveals a six-coordinate, hs-\( \text{Fe}^{II} \) complex with the new amide group bound in the open site (Figure 5). Reaction of 5 with \( \text{BuOOH} \) (10 equiv) at room temperature does not induce arene hydroxylation as seen for 3 but instead gives rise to a transient green intermediate that rapidly decays (\( \approx t_{1/2} < 30 \text{ s} \)). This intermediate can be trapped at \(-30 ^\circ \text{C} \), revealing a long-lived, dark-blue species with \( \lambda_{\text{max}} = 606 \text{ nm} \) (\( \epsilon = 2100 \text{ M}^{-1} \text{ cm}^{-1} \) based on total Fe), which rapidly decays upon warming without any ligand hydroxylation (Figures S22, S23). Resonance Raman spectroscopy of the 606 nm species (6) shows vibrations at 642 and 876 cm\(^{-1}\), which are typical of hs-\( \text{Fe}^{III} \)OOR species and can be assigned to \( \nu(\text{Fe}=\text{O}) \) and \( \nu(\text{O}=\text{O}) \) (Figure S21), respectively. EPR revealed hs-\( \text{Fe}^{III} \) peaks (g 7.89, 5.55, 4.24), along with a minor, unidentified ls-\( \text{Fe}^{III} \) component (\( \approx 20\% \)). Based on these data, a reasonable structure for the blue species is proposed for complex 6 as shown in Figure 5.

DFT calculations (see Supporting Information) fully support the proposed, hs-\( \text{Fe}^{III} \)–OOR structure with an amide N–H···O bond. The influence of H-bond donors on the stability of iron–oxygen species in nonheme Fe systems is of great interest but is still not well-understood.\(^1\) We conclude that the amide group in 5 helps to trap an Fe\(^{III} \)–OOR complex, in contrast to 3, which likely forms an \( \text{Fe}^{III} \)–OOR species as a transient intermediate during arene hydroxylation.

We have employed an experimental and computational approach to examine the influence of secondary coordination sphere modifications in nonheme iron model complexes. The results herein give new insights regarding how nonheme Fe enzymes may utilize two critical secondary coordination sphere effects, substrate orientation, and hydrogen bonding, to control reactivity.
