Abstract

An oriented hypergraph is an oriented incidence structure that generalizes and unifies graph and hypergraph theoretic results by examining its locally signed graphic substructure. In this paper we obtain a combinatorial characterization of the coefficients of the characteristic polynomials of oriented hypergraphic Laplacian and adjacency matrices via a signed hypergraphic generalization of basic figures of graphs. Additionally, we provide bounds on the determinant and permanent of the Laplacian matrix, characterize the oriented hypergraphs in which the upper bound is sharp, and demonstrate that the lower bound is never achieved.

Keywords: Laplacian matrix, adjacency matrix, oriented hypergraph, characteristic polynomial.

2010 MSC: 05C50, 05C65, 05C22

1. Introduction

Sachs’ Coefficient Theorem provides a combinatorial interpretation of the coefficients of the characteristic polynomial of the adjacency matrix of a graph as families of sub-graphs \textsuperscript{11}, this was recently extended to signed graphs in \textsuperscript{11}. In this paper we obtain an oriented hypergraphic generalization of Sachs’ Coefficient Theorem that extends to the oriented hypergraphic Laplacian and the signless Laplacian. This extension shows that the standard adjacency matrix coefficients are the restricted enumeration of a family of sub-incidence-structures associated to any finite integral incidence matrix — providing a single class of combinatorial objects to study the coefficients of both characteristic polynomials.

These theorems are unified and generalized by using the weak walk Theorem for oriented hypergraphs in \textsuperscript{11}, which unifies the entries of the oriented hypergraphic matrices as weak walk counts, then constructing incidence preserving maps from disjoint 1-paths into a given oriented hypergraph. Restrictions of these maps to adjacency preserving maps on sub-oriented-hypergraphs obtained by weak deletion of vertices allows for the reclaiming of basic figures of graphs, as well as the determinant of the adjacency matrix by cycle covers.

\textsuperscript{2}Portions of these results appear in 2017 Master’s Thesis.
The necessary oriented hypergraphic background and Sachs’ Theorem are collected in Section 2. In Section 3 we examine the relationship between incidence preserving maps, weak walks, and generalized cycle covers called contributors. Section 4 establishes the permanent and determinant of the adjacency and Laplacian matrices as contributor counts as well as the main coefficient theorems of determinant and permanent versions of the characteristic polynomials. Finally, contributor counts are used to provide upper and lower bounds for the determinant and permanent of the Laplacian matrix over all orientations of a given underlying hypergraph. The lower bound is shown to never be sharp, while the family of oriented hypergraphs that achieve the upper bound are characterized.

2. Background

2.1. Oriented Hypergraphs

These definitions are an adaptation of those appearing in [12, 11, 4], and allow for oriented hypergraphs to be treated as locally signed graphic through its adjacencies.

An oriented hypergraph is a quintuple \((V, E, \mathcal{I}, \iota, \sigma)\) where \(V\), \(E\), and \(\mathcal{I}\) denote disjoint sets of vertices, edges, and incidences, respectively, with incidence function \(\iota : \mathcal{I} \rightarrow V \times E\), and orientation function \(\sigma : \mathcal{I} \rightarrow \{+1, -1\}\). We say \(v\) and \(e\) are incident along \(i\) if \(\iota(i) = (v, e)\). Two incidences \(i\) and \(j\) are said to be parallel if \(\iota(i) = \iota(j)\) — this provides an equivalence class of parallel incidences where the size of each equivalence class is called the multiplicity of the incidence.

![Figure 1: An oriented hypergraph.](image)

The degree of vertex \(v\) is \(\deg(v) := |\{i \in \mathcal{I} \mid (\text{proj}_V \circ \iota)(i) = v\}|\), while the size of an edge \(e\) is \(\text{size}(e) := |\{i \in \mathcal{I} \mid (\text{proj}_E \circ \iota)(i) = e\}|\). Vertices \(v\) and \(w\) are said to be adjacent with respect to edge \(e\) if there are incidences \(i \neq j\) such that \(\iota(i) = (v, e)\) and \(\iota(j) = (w, e)\). A directed adjacency is a quintuple \((v, i, e, j, w)\) where \(v\) and \(w\) are adjacent with respect to edge \(e\) using incidences \(i\) and \(j\). Observe that if the directed adjacency \((v, i, e, j, w)\) exists, then the opposite directed adjacency \((w, j, e, i, v)\) also exists. An adjacency is the set associated to a directed adjacency (or its opposite). Dropping the symmetric directedness condition...
allows for directed oriented hypergraphic results to be studied. The *sign of the adjacency* \((v, i, e, j, w)\) is

\[
\text{sgn}(v, i, e, j, w) = -\sigma(i)\sigma(j),
\]

and \(\text{sgn}(v, i, e, j, w) = 0\) if \(v\) and \(w\) are not adjacent. *Weak deletion of vertex* \(v\) is the oriented hypergraph obtained by deleting vertex \(v\) and all incidences containing \(v\) — note this does not delete edges.

### 2.2. Weak Walks

A *(directed)* weak walk is a sequence

\[
W = (a_0, i_1, a_1, i_2, a_2, i_3, a_3, \ldots, a_{n-1}, i_n, a_n)
\]

of vertices, edges and incidences, where \(\{a_k\}\) is an alternating sequence of vertices and edges, and \(i_k\) is an incidence between \(a_{k-1}\) and \(a_k\); specifically, \(\{(\text{proj}_V \circ \iota)(i_k), (\text{proj}_E \circ \iota)(i_k)\} = \{a_{k-1}, a_k\}\). Similar to directed adjacencies, a weak walk is the set associated to a directed weak walk. The prefix vertex/edge/cross is used when the end points of a weak walk are vertices/edges/one edge and one vertex. The length of a weak walk is half the number of incidences in the weak walk.

A vertex walk is a weak walk where \(a_0, a_n \in V\), and \(i_2k-1 \neq i_{2k}\), and an adjacency is a vertex walk of length 1. A vertex backstep is a weak walk of length 1 of the form \((v, i, e, i, v)\), while a loop is a vertex walk of the form \((v, i, e, j, v)\) where \(i \neq j\). A vertex path is a vertex walk where no vertex or edge is repeated, while a circle is a vertex path except \(a_0 = a_n\). Analogous edge-centric definitions exist for the incidence dual and the results are inherited.

The *sign of a weak walk* \(W\) is

\[
\text{sgn}(W) = (-1)^{\left\lfloor n/2 \right\rfloor} \prod_{h=1}^{n} \sigma(i_h),
\]

which is equivalent to taking the product of the signed adjacencies if \(W\) is a vertex walk; see [14, 15, 8] for bidirected graphs as orientations of signed graphs.

### 2.3. Oriented Hypergraphic Matrices

The vertices and edges of an oriented hypergraph \(G\) are regarded as totally ordered as the row and column labels of a given \(V \times E\) incidence matrix \(H_G\) where the \((v, e)\)-entry is the sum of all \(\sigma(i)\) such that \(i(i) = (v, e)\). The adjacency matrix \(A_G\) of an oriented hypergraph \(G\) is the \(V \times V\) matrix whose \((v, w)\)-entry is the sum of all signed adjacencies from \(v\) to \(w\). The degree matrix of an oriented hypergraph \(G\) is the \(V \times V\) diagonal matrix \(D_G := \text{diag}(\deg(v_1), \ldots, \deg(v_n))\). The Laplacian matrix of \(G\) is defined as \(L_G := H_GH_G^T = D_G - A_G\) for all oriented hypergraphs.

The (vertex) *weak walk matrix of length* \(k\) is the matrix \(W_{(G, V, V, k)}\) whose \((v, w)\)-entry is the number of positive weak walks of length \(k\) from \(v\) to \(w\) minus the number of negative weak walks of length \(k\) from \(v\) to \(w\). It was shown in [14] for incidence-simple oriented hypergraphs, and improved to all oriented hypergraphs in [4], that the entries of oriented hypergraphic matrices are weak walk counts.
Theorem 2.3.1. Let $G$ be an oriented hypergraph.

1. The $(v, w)$-entry of $D_G$ is the number of strictly weak, weak walks, of length 1 from $v$ to $w$. That is, the number of backsteps from $v$ to $w$.

2. The $(v, w)$-entry of $A_G$ is the number of positive (non-weak) walks of length 1 from $v$ to $w$ minus the number of negative (non-weak) walks of length 1 from $v$ to $w$.

3. The $(v, w)$-entry of $-L_G$ is the number of positive weak walks of length 1 from $v$ to $w$ minus the number of negative weak walks of length 1 from $v$ to $w$. That is, $-L_G = W_{(G; V), (V; 1)}$.

Powers of these matrices extend to weak walks of length $k$, for non-negative integers $k$, while entries of $H_G$ are half-walks.

2.4. Sachs’ Theorem

Sachs’ Theorem provides a combinatorial count for the coefficients of the characteristic polynomial of the adjacency matrix of a graph, for an expanded development see [7].

An elementary figure is either a link graph or a cycle on $n$ vertices where $n \geq 1$. A basic figure $U$ is a graph that is the disjoint union of elementary figures. Let $\mathcal{U}_k$ denote the set of all basic figures that are contained in $G$ and have exactly $k$ isolated vertices, let $p(U)$ be the number of elementary figures of $U$ and let $c(U)$ denote the number of circuits in $U$.

Theorem 2.4.1 (Sachs’ Theorem). For a graph $G$ with $n = |V(G)|$,

$$
\chi_G(A, x) = \sum_{k=1}^{n} \left( \sum_{U \in \mathcal{U}_k} (-1)^{p(U)} (2)^{c(U)} \right) x^k.
$$

Sachs’ Theorem has been generalized to signed graphs in [1]. While alternate proofs of the Laplacian and signless Laplacian of a graph also appear in [2] and [3], we generalize Sachs’ Theorem to oriented hypergraphs for both the adjacency and Laplacian matrices (the signless Laplacian is contained as a specific orientation) using a single universal combinatorial interpretation of coefficients for both determinant and permanent based characteristic polynomial.

3. Incidence Preserving Maps

3.1. Contributors as Generalized Basic Figures

The incidence preserving maps introduced in this section are motivated by the directed graphic version of monic, adjacency-preserving, path embeddings into circuit graphs appearing in [4] as a study of $\Phi$-injectivity classes.

Given hypergraphs $H = (V_H, E_H, I_H, \iota_H)$ and $G = (V_G, E_G, I_G, \iota_G)$ with no isolated vertices or 0-edges, an incidence preserving map is a function $\alpha : H \to G$ such that the following diagram commutes:
Lemma 3.1.1. Let $\overrightarrow{P}_k$ be a directed vertex path graph of length $k$. $W$ is a vertex weak walk of length $k$ in $G$ if, and only if, there is an incidence preserving map $\omega: \overrightarrow{P}_k \to G$ such that $\omega(\overrightarrow{P}_k) = W$.

Proof. Let $\overrightarrow{P}_k$ be the directed vertex path

$$(v_0, i_1, e_1, i_2, v_1, i_3, e_2, ..., e_k, i_{2k}, v_k)$$

and let

$$W = (a_0, j_1, a_1, j_2, a_2, j_3, a_3, ..., a_{2k-1}, j_{2k}, a_{2k})$$

be a vertex weak walk in $G$. The map $\omega: \overrightarrow{P}_k \to G$ where $\omega(v_b) = a_{2b}$, $\omega(e_b) = a_{2b-1}$, $\omega(i_b) = j_b$ is the unique incidence preserving map from $\overrightarrow{P}_k$ to $W$.

Moreover, if $\overrightarrow{P}_k$ maps into $G$ via an incidence preserving map $\omega$, then $\omega(\overrightarrow{P}_k)$ is determined by the sequence of (possibly repeating) incidences in $G$, hence is a weak walk in $G$. $\square$

From here we are able to restate the weak walk Theorem for $L_G$ from [11, 4] in terms of incidence preserving maps.

Theorem 3.1.2. The $(v, w)$-entry of $L_G$ is

$$\sum_{\omega \in \Omega_1} -\text{sgn}(\omega(\overrightarrow{P}_1)),$$

where $\overrightarrow{P}_1 = (t, i, e, j, h)$ and $\Omega_1$ is the set of all incidence preserving maps $\omega: \overrightarrow{P}_1 \to G$ with $\omega(t) = v$ and $\omega(h) = w$.

A contributor of $G$ is an incidence preserving map from a disjoint union of $\overrightarrow{P}_1$’s into $G$ defined by $c: \bigsqcup_{e \in E} \overrightarrow{P}_1 \to G$ such that $c(t_e) = v$ and $\{c(h_e) | v \in V\} = V$. Let $C(G)$ denote the set of contributors.

By definition, each contributor creates a natural bijection from the vertex set to itself.

Lemma 3.1.3. Every contributor $c$ is associated to a single permutation $\pi \in S_V$, the symmetric group on vertex set $V$.

Two contributors that are associated to the same permutation $\pi$ are said to be $\pi$-permutomorphic, let $C_\pi(G)$ denote the equivalence class of $\pi$-permutomorphic contributors. Observe that $\pi$-permutomorphic contributors need not be isomorphic for if $c(h_v) = v$ the associated algebraic 1-cycle may be a result of either a loop or a backstep. Similarly, an algebraic 2-cycle may arise from a repeated adjacency or two distinct
adjacencies. An algebraic 2-cycle that corresponds to a repeated adjacency is called a *degenerate 2-circle*. This is an important distinction because a 2-circle has two possible cycle orientations, while a degenerate 2-circle has only one orientation.

**Lemma 3.1.4.** Permutomorphic contributors are isomorphic up to interchanging backsteps and loops, and interchanging of 2-circles and degenerate 2-circles.

Figure 2 below contains some contributors of $G$ from Figure 1 grouped by permutation classes.

Figure 2: Examples of elements in $\mathcal{C}_{(123)}(G)$ and $\mathcal{C}_{(12)}(G)$ for the oriented hypergraph in Figure 1.

Let $\mathcal{C}_{sk}(G)$ denote the set of contributors of $G$ with exactly $k$ backsteps, and let $\mathcal{C}_{sk}(G)$ denote the set of contributors of $G$ with at least $k$ backsteps. Define $\mathcal{C}_{sk}(G)$ as the collection of sub-contributors of $G$ formed from the contributors of $\mathcal{C}_{sk}(G)$ by deleting exactly $k$ backsteps while retaining the $k$ isolated vertices. Similarly, define $\mathcal{C}_{sk}(G)$ as the collection of sub-contributors of $G$ formed from the contributors of $\mathcal{C}_{sk}(G)$ by deleting exactly $k$ backsteps while retaining the $k$ isolated vertices. Observe that $\mathcal{C}_{s0}(G) = \mathcal{C}_{s0}(G) = \mathcal{C}(G)$, while $\mathcal{C}_{sk}(G)$ generalizes basic figures of a graph.

**Lemma 3.1.5.** For a graph $G$, $\mathcal{C}_{sk}(G)$ is the set of oriented basic figures with $k$ isolated vertices.

A *cycle cover* of a graph $G$ is a union of disjoint cycles which are subgraphs of $G$ and contain all of the vertices of $G$. Notice that the cycle covers of a graph are simply the contributors that do not contain any backsteps.

**Lemma 3.1.6.** For a graph $G$, $\mathcal{C}_{s0}(G) = \mathcal{C}_{s0}(G)$ is the set of oriented cycle covers.
We say two elements of $\mathcal{C}_k(G)$ (resp. $\mathcal{C}_{2k}(G)$) are $\pi$-permumorphic if they extend to the same $\pi$-permutomorphism class $\mathcal{C}_\pi(G)$ via the introduction of $k$ backsteps that exist in $G$. Let $\mathcal{C}_{2k,\pi}(G)$ (resp. $\mathcal{C}_{2k}(G)$) be the set of $\pi$-permumorphic elements of $\mathcal{C}_k(G)$ (resp. $\mathcal{C}_{2k}(G)$).

4. General Coefficient Theorems

4.1. Permanents and Determinants

Let $ce(c)$, $oc(c)$, $pe(c)$ and $ne(c)$ be the number of even, odd, positive, and negative circles in a contributor $c$, respectively. The necessity for these counts are related to the differences between balanced (all circles positive) signed graphs and the classical development of hypergraph theory. An ordinary graph may be regarded as a signed graph with all edges positive, hence all circles are positive, which leads to many graph theoretic theorems having a balanced signed graphic analogs (see [14, 15]). The classical development of hypergraphs (see [2, 3]) uses a $(0,1)$-incidence matrix equivalent where a circle is positive if, and only if, it is even. Oriented hypergraphs allow for a locally signed graphic approach to separate the concepts of even from positive and odd from negative; additional combinatorial properties and applications can be found in [5, 6, 13].

**Theorem 4.1.1.** Let $G$ be an oriented hypergraph with adjacency matrix $A_G$ and Laplacian matrix $L_G$, then

1. $\text{perm}(L_G) = \sum_{c \in \mathcal{C}_{2\tau}(G)} (-1)^{oc(c) + ne(c)}$,
2. $\text{det}(L_G) = \sum_{c \in \mathcal{C}_{\tau}(G)} (-1)^{pc(c)}$,
3. $\text{perm}(A_G) = \sum_{c \in \mathcal{C}_{\tau}(G)} (-1)^{nc(c)}$,
4. $\text{det}(A_G) = \sum_{c \in \mathcal{C}_{\tau}(G)} (-1)^{ec(c) + ne(c)}$.

**Proof.** Proof of 1. From the definition and Theorem 3.1.2 we have

$$\text{perm}(L_G) = \sum_{\pi \in \mathcal{S}_V} \prod_{v \in V} \sum_{\omega \in \Omega_{1,\pi}} -\text{sgn}(\omega(\overrightarrow{P}_1)),$$

where $\Omega_{1,\pi}$ is the set of all incidence preserving maps $\omega : \overrightarrow{P}_1 \to G$ with $\omega(t) = v$ and $\omega(h) = \pi(v)$.

Distributing the inner sums for all $v \in V$ (without evaluating the inner sums), passes from incidence preserving maps $\omega : \overrightarrow{P}_1 \to G$ with $\omega(t) = v$ and $\omega(h) = \pi(v)$ to incidence preserving maps $c : \prod_{v \in V} \overrightarrow{P}_1 \to G$ with $\omega(t_v) = v$, $\omega(h_v) = \pi(v)$, and $\{\omega(h_v) \mid v \in V\} = V$. Collecting permumorphic contributors gives:

$$\text{perm}(L_G) = \sum_{\pi \in \mathcal{S}_V} \sum_{c \in \mathcal{C}_{\pi}(G)} \prod_{v \in V} \sigma(c(i_v))\sigma(c(j_v)).$$

To calculate the product $\prod_{v \in V} \sigma(c(i_v))\sigma(c(j_v))$ first factor out $-1$ for each adjacency determined by $c$, producing a factor of $(-1)^{oc(c)}$. This forces every negative adjacency in $G$ appear as a value of $-1$ in $L_G$.
and every positive adjacency in \(G\) to appear as a +1, since \(L_G = D_G - A_G\). Now factor out \(-1\) from every adjacency that is negative in \(G\), producing a factor of \((-1)^{nc(c)}\) and a net factor of \((-1)^{oc(c)+nc(c)}\). Thus,

\[
\text{perm}(L_G) = \sum_{\pi \in S_V} \sum_{c \in \pi(G)} (-1)^{oc(c)+nc(c)},
\]

and combine to get

\[
\text{perm}(L_G) = \sum_{c \in \mathbb{C}(G)} (-1)^{oc(c)+nc(c)}.
\]

**Proof of 2.** With the inclusion of the sign of the permutation the proof is identical until

\[
\text{det}(L_G) = \sum_{\pi \in S_V} (-1)^{cc(\pi)} \sum_{c \in \mathbb{E}_+(G)} (-1)^{oc(c)+nc(c)}
\]

\[
= \sum_{\pi \in S_V} \sum_{c \in \mathbb{E}_+(G)} (-1)^{cc(\pi)+oc(c)+nc(c)}.
\]

However, all of the even cycles in \(\pi\) correspond to even circles in all corresponding contributors so

\[
\text{det}(L_G) = \sum_{c \in \mathbb{E}_+(G)} (-1)^{pc(c)}
\]

**Proofs of 3 and 4.** The adjacency matrix theorems in parts 3 and 4 are proved similarly, but with the following changes. First, the incidence preserving maps \(\omega\) are replaced with adjacency preserving maps \(\omega'\) with the same properties. Second, there is no need to factor out a negative from each adjacency as their signs are accurately represented in the adjacency matrix. Finally, the sum is over backstep-free contributors since all the only non-adjacency preserving \(\omega\)'s are backsteps.

**Remark 4.1.2.** As a result from the proof of part 1 of Theorem 4.1.1 a backstep is not considered a circle of a contributor while a loop is considered a circle. However, from the proof of part 2 any component of a contributor that corresponds to an algebraic 2-cycle is considered a circle of a contributor.

### 4.2. Coefficient Theorems

Let \(\chi^D(M, x) := \text{det}(xI - M)\) be the determinant-based characteristic polynomial and \(\chi^P(M, x) := \text{perm}(xI - M)\) be the permanent-based characteristic polynomial. Let \(bs(c)\) be the number of backsteps in contributor \(c\).

**Theorem 4.2.1.** Let \(G\) be an oriented hypergraph with adjacency matrix \(A_G\) and Laplacian matrix \(L_G\), then

1. \(\chi^P(A_G, x) = \sum_{k=0}^{V_1} \left( \sum_{c \in \mathbb{E}_{+k}(G)} (-1)^{oc(c)+nc(c)} \right) x^k\),
2. \( \chi^D(A_G, x) = \sum_{k=0}^{\lvert V \rvert} \sum_{c \in \mathbb{Z}_+} (-1)^{pc(c)} x^k \),
3. \( \chi^P(L_G, x) = \sum_{k=0}^{\lvert V \rvert} \sum_{c \in \mathbb{Z}_+} (-1)^{nc(c)+bs(c)} x^k \),
4. \( \chi^D(L_G, x) = \sum_{k=0}^{\lvert V \rvert} \sum_{c \in \mathbb{Z}_+} (-1)^{cc(c)+nc(c)+bs(c)} x^k \).

Before proving the theorem, observe that the presentation of parts 1-4 have adjacency and Laplacian matrices reversed from Theorem 4.1.1; this is done as the proofs are parallel based on the appearance of \(-A\).

**Proof. Proof of 1.** First introduce a choice function \( \alpha \) for a given permutation \( \pi \) and vertex \( v \) where \( \alpha : v \to \left\{ x \cdot \delta(v, \pi(v)), \sum_{\omega' \in \Omega_{1, \pi}'} \sgn(\omega'(\widetilde{P}_1)) \right\} \), where \( \Omega_{1, \pi}' \) is the set of all adjacency preserving maps \( \omega' : \widetilde{P}_1 \to G \) such that \( \omega'(t) = v \) and \( \omega'(h) = \pi(v) \). Let \( A_\pi \) be the set of all such \( \alpha \)'s for a given \( \pi \).

Observe that if \( \pi(v) = v \), then \( \alpha \) maps \( v \) to either \( x \) or \( \sum_{\omega' \in \Omega_{1, \pi}'} \sgn(\omega'(\widetilde{P}_1)) = (v, v) \)-entry of \( A_G \).

However, if \( \pi(v) \neq v \), then \( \alpha \) maps \( v \) to either 0 or \( \sum_{\omega' \in \Omega_{1, \pi}'} \sgn(\omega'(\widetilde{P}_1)) = (v, \pi(v)) \)-entry of \( A_G \). Thus, \( \chi^P(A_G, x) \) can be written as

\[
\chi^P(A_G, x) = \perm(xI - A_G) = \sum_{\pi \in S_V} \prod_{v \in V} \alpha(v).
\]

Distributing we get

\[
= \sum_{\pi \in S_V} \sum_{\beta \in \mathcal{B}_\pi} \prod_{v \in V} \beta(v),
\]

where \( \mathcal{B}_\pi \) is the set of all functions \( \beta : V \to \left\{ x \cdot \delta(v, \pi(v)), \sum_{\omega' \in \Omega_{1, \pi}'} \sgn(\omega'(\widetilde{P}_1)) \right\} \).

Write \( \mathcal{B}_\pi = \mathcal{B}_\pi^0 \cup \mathcal{B}_\pi^1 \) where \( \mathcal{B}_\pi^0 \) is the set of all \( \beta \) maps with \( \beta(v) = x \cdot \delta(v, \pi(v)) \) for some non-fixed point \( v \), and \( \mathcal{B}_\pi^1 \) is its complement. For every \( \beta \in \mathcal{B}_\pi^0 \), \( \prod_{v \in V} \beta(v) = 0 \), since there is a non-fixed point \( v \) with \( \beta(v) = x \cdot \delta(v, \pi(v)) = 0 \). Now partition \( \mathcal{B}_\pi^1 \) into \( \bigcup_{k=0}^{\lvert V \rvert} \mathcal{B}_{k, \pi} \), where \( \mathcal{B}_{k, \pi} \) is the set of all \( \beta \in \mathcal{B}_\pi^1 \) such that \( \lvert \beta^{-1}(x) \rvert = k \). For each \( \beta \in \mathcal{B}_{k, \pi} \) let \( U_\beta \subseteq V \) be the set of \( \lvert V \rvert - k \) vertices not mapped to \( x \) by \( \beta \), giving

\[
= \sum_{\pi \in S_V} \sum_{k=0}^{\lvert V \rvert} \sum_{\beta \in \mathcal{B}_{k, \pi}} \left( \prod_{v \in U_\beta} \beta(v) \right) x^k.
\]

Let \( \Omega_{1, \pi}'[U_\beta] \) be the set of adjacency preserving maps \( \omega' : \widetilde{P}_1 \to (G \setminus \overline{U}_\beta) \) such that \( \omega'(t) = v \), \( \omega'(h) = \pi(v) \), and \( G \setminus \overline{U}_\beta \) is the oriented-hypergraph resulting from the weak-deletion of vertices of \( U_\beta \) and the deletion of any resulting 0-edges. Evaluating \( \beta(v) \) gives

\[
= \sum_{\pi \in S_V} \sum_{k=0}^{\lvert V \rvert} \sum_{\beta \in \mathcal{B}_{k, \pi}} \left( \prod_{v \in U_\beta} \omega'(\omega'_{\pi, \pi}[U_\beta]) \right) x^k.
\]
and distributing again produces
\[
\begin{aligned}
\sum_{\pi \in \mathcal{S}_V} \prod_{k=0}^{|V|} \sum_{c \in \mathcal{E}_{0,v}(G \setminus \overline{U}_\beta)} \prod_{v \in U_\beta} \sigma(c(i_v)) \sigma(c(j_v)) x^k,
\end{aligned}
\]
where \( \mathcal{E}_{0,v}(G \setminus \overline{U}_\beta) \) is the set of all backstep-free permutomorphic contributors \( c : \bigcup_{v \in U_\beta} \overrightarrow{P}_1 \rightarrow (G \setminus \overline{U}_\beta) \)
with \( c(t_v) = v, c(h_v) = \pi(v) \), and \( \{ c(h_v) \mid v \in U_\beta \} = U_\beta \).

Note the \( \omega' \in \Omega_{1,\pi}[U_\beta] \) are adjacency preserving so any 1-edges resulting from weak deletion of \( \overline{U}_\beta \)
cannot be mapped onto as backsteps. As a result, weak-deletion is not needed, and the sub-hypergraph
induced on vertex set \( U_\beta \) would be sufficient. However, the preservation of all the incidences containing \( U_\beta \)
is necessary for incidence preserving maps when determining Laplacian coefficients. Thus, \( G \setminus \overline{U}_\beta \) is the
smallest sub-object in which all results are true.

Factoring out \(-1\) as in the proof for part 1 of Theorem 4.1.1 gives
\[
\begin{aligned}
\sum_{\pi \in \mathcal{S}_V} \prod_{k=0}^{|V|} \sum_{c \in \mathcal{E}_{0,v}(G \setminus \overline{U}_\beta)} (-1)^{oc(c)+nc(c)} x^k,
\end{aligned}
\]

Again, the \( \beta \in \mathcal{B}_{k,\pi} \) are determined by \( \overline{U}_\beta \subseteq V \) and \( c \in \mathcal{E}_{0,\pi}(G \setminus \overline{U}_\beta) \) are backstep-free contributors on \( U_\beta \). Observe that for each \( c \in \mathcal{E}_{0,\pi}(G \setminus \overline{U}_\beta) \) there is a natural extension to \( G \) via elements of \( \mathcal{E}_{k,\pi}(G) \) by
including an isolated vertex for each vertex in \( \overline{U}_\beta \). Specifically, the extension factors
\[
\begin{aligned}
\bigcup_{v \in U_\beta} \overrightarrow{P}_1 \cup \overline{U}_\beta \xrightarrow{c \in \mathcal{E}_{k,\pi}(G)} G
\end{aligned}
\]
and combines the sum as
\[
\begin{aligned}
\sum_{\pi \in \mathcal{S}_V} \prod_{k=0}^{|V|} \sum_{c \in \mathcal{E}_{k,\pi}(G)} (-1)^{oc(c)+nc(c)} x^k,
\end{aligned}
\]
where the elements of \( \mathcal{E}_{k,\pi}(G) \) are backstep-free with \( k \) isolated vertices (which determine \( \overline{U}_\beta \)) and adjacency
preserving on the non-isolated vertices.

Reverse the order of the first two summations and combining permutomorphic contributors as in Theorem
4.1.1 yields
\[
\begin{aligned}
\sum_{k=0}^{|V|} \sum_{c \in \mathcal{E}_{k}(G)} (-1)^{oc(c)+nc(c)} x^k.
\end{aligned}
\]
Completing the proof for part 1.
Proof of 2. Mirrors the proof of part 2 in Theorem \ref{thm:sachs}. The inclusion of the sign of the permutation the proof is identical until

\[
\chi^D(A_G, x) = \sum_{k=0}^{|V|} \sum_{\pi \in \mathcal{S}_V} (-1)^{cc(\pi)} \left[ \left( \sum_{c \in \mathcal{E}_{\leq 0}(G)} \left( -1 \right)^{oc(c)+nc(c)} \right) x^k \right]
\]

First, replace adjacency preserving maps with incidence preserving maps. Second, \(xI - L_G\) has the sign of adjacencies represented correctly while the degrees are negated, so factor out a \(-1\) for each backstep to produce \((-1)^{bs(c)}\), and then factor out a \(-1\) for each negative adjacency producing \((-1)^{nc(c)}\). Finally, distributing incidence preserving maps produces an inner sum over \(\mathcal{E}_{\leq 0}(G \setminus \overline{U}_\beta)\).

Proofs of 3 and 4. Both \(\chi^D(L_G, x)\) and \(\chi^P(L_G, x)\) are proved similarly, but with the following changes. First, replace adjacency preserving maps with incidence preserving maps. Second, \(xI - L_G\) has the sign of adjacencies represented correctly while the degrees are negated, so factor out a \(-1\) for each backstep to produce \((-1)^{bs(c)}\), and then factor out a \(-1\) for each negative adjacency producing \((-1)^{nc(c)}\). Finally, distributing incidence preserving maps produces an inner sum over \(\mathcal{E}_{\leq 0}(G \setminus \overline{U}_\beta)\).

Remark 4.2.2. Sachs’ Theorem (Theorem \ref{thm:sachs}) is a corollary of Theorem \ref{thm:perm} if \(G\) is a graph and oriented circles are combined.

Remark 4.2.3. Comparing \(\text{perm}(-L_G) = \chi^P(L_G, 0)\) we see

\[
\sum_{c \in \mathcal{E}_{\leq 0}(G)} (-1)^{oc(c)+nc(c)+|V|} = \sum_{c \in \mathcal{E}_{\leq 0}(G)} (-1)^{nc(c)+bs(c)}.
\]

This suggests the parity of \(bs(c)\) is equal to the parity of \(oc(c) + |V|\). This can easily be verified directly by cases, and helps translate between Theorems \ref{thm:sachs} and \ref{thm:perm}.

4.2.1. Examples

\(A_G\) for an oriented 3-circuit. Consider the incidence-oriented 3-circuit in Figure \ref{fig:3-circuit} below with its contributors grouped by permutomorphism classes.
The oriented 3-circuit has adjacency matrix

$$A_G = \begin{bmatrix}
0 & 1 & 1 \\
1 & 0 & -1 \\
1 & -1 & 0
\end{bmatrix}$$

with $\chi^D(A_G, x) = x^3 - 3x + 2$. From part 2 of Theorem 4.2.1 the sub-contributor signing function is $(-1)^{pc(c)}$. Observe that there are only two backstep-free contributors, each with 0 positive circles, so the constant is $(-1)^0 + (-1)^0 = 2$.

The coefficient of $x^1$ is the signed sum of elements of $\mathcal{C}_{a1}(G)$. The elements of $\mathcal{C}_{a1}(G)$ for the incidence-oriented 3-circuit are:

From Figure 4 we see there are three elements in $\mathcal{C}_{a1}(G)$, each with a single degenerate 2-circle (which are necessarily positive) so the coefficient of $x^1$ is $(-1)^1 + (-1)^1 + (-1)^1 = -3$. 

Figure 3: An incidence-oriented 3-circuit and its contributors grouped by permutomorphism classes.

Figure 4: Elements of $\mathcal{C}_{a1}(G)$ for an incidence-oriented 3-circuit grouped by permutomorphism classes.
The remaining coefficients are obtained by observing that $\mathcal{E}_{\pm|V|-1}(G)$ is necessarily empty, and $\mathcal{E}_{\pm|V|}(G)$ only contains the set of isolated vertices.

$L_G$ for an oriented 3-circuit. The oriented 3-circuit in Figure 3 has Laplacian matrix

$$L_G = \begin{bmatrix} 2 & -1 & -1 \\ -1 & 2 & 1 \\ -1 & 1 & 2 \end{bmatrix}$$

with $\chi^D(L_G, x) = x^3 - 6x^2 + 9x - 4$. From part 4 of Theorem 4.2.1 the sub-contributor signing function is $(-1)^{ec(e)+ne(e)+bs(e)}$. The contributors in the first column in Figure 3 are all $-1$ while the remaining three columns sum each sum to 0, producing a constant $-4$.

The coefficient of $x^1$ is the signed sum of elements of $\mathcal{E}_{\pm 1}(G)$. The elements of $\mathcal{E}_{\pm 1}(G)$ for the incidence-oriented 3-circuit are:

From Figure 3 there are fifteen elements in $\mathcal{E}_{\pm 1}(G)$, the twelve arising from the identity permutation are $+1$ while the three with degenerate 2-circles are $-1$, producing a coefficient of $12 - 3 = +9$ for $x^1$.

The remaining coefficients can be checked similarly.

An extroverted 3-edge. Consider the extroverted-oriented 3-edge in and its contributors in Figure 6.
Figure 6: An incidence-oriented 3-edge and its contributors grouped by permutomorphism classes.

The extroverted 3-edge has adjacency matrix

\[ A_G = \begin{bmatrix}
0 & -1 & -1 \\
-1 & 0 & -1 \\
-1 & -1 & 0
\end{bmatrix} \]

with \( \chi^D(A_G, x) = x^3 - 3x + 2 \), and Laplacian matrix

\[ L_G = \begin{bmatrix}
1 & 1 & 1 \\
1 & 1 & 1 \\
1 & 1 & 1
\end{bmatrix} \]

with \( \chi^D(L_G, x) = x^3 - 3x^2 \).

The constant of \( \chi^D(A_G, x) \) is 2 as there are only two backstep-free contributors, each with 0 positive circles. The constant of \( \chi^D(L_G, x) \) is 0 as the contributors in the top row contributors cancel those in the bottom row. The remaining coefficients can be checked by referring to Figure 6.

4.3. Optimizing Permanents and Determinants

Theorems 4.1.1 and 4.2.1 allow for the study of optimizing permanents and determinants through contributors. The bounds presented are for integral incidence matrices — it may be possible to sharpen of the bounds via complex unit orientations by combining with the work from [4] and [10].

**Theorem 4.3.1.** For a fixed underlying oriented hypergraph \( G \) with no isolated vertices, no 0-edges, and varied orientation function \( \sigma \), the following are equivalent:
1. \( \text{perm}(L_G) \) is maximized over all orientations \( \sigma \),

2. \( \sigma \) is the all extroverted or all introverted orientation,

3. \( L_G \) is the signless Laplacian,

4. \( \text{perm}(L_G) = |\mathcal{C}(G)| \).

**Proof.** Part 2 and 3 are trivially equivalent. To see the equivalence of parts 1 and 3 observe that in the signless Laplacian a circle in an associated contributor is negative if, and only if, it is odd. From Theorem 4.1.1 \( \text{perm}(L_G) \) is maximal when, for every contributor \( c \), \( oc(c) \) and \( nc(c) \) have the same parity. However, if \( oc(c) \neq nc(c) \), then there either exists a circle in a contributor which is either odd and not negative, or negative and not odd. Refine the corresponding algebraic cycle into fixed elements causing each element in the circle to become a backstep, forming a new contributor \( c' \). The parity of \( oc(c') \) and \( nc(c') \) are not equal, so \( oc(c) = nc(c) \) for all \( c \in \mathcal{C}(G) \).

Moreover, when \( oc(c) = nc(c) \) for all contributors \( c \), then a circle of \( c \) is odd if, and only if, it is negative by a similar refinement argument as above. Thus, \( \text{perm}(L_G) \) is maximal if, and only if, \( L_G \) is the signless Laplacian.

The equivalence for part 4 is obvious by Theorem 4.1.1. \( \square \)

**Theorem 4.3.2.** Let \( G \) be an oriented hypergraph with no isolated vertices or 0-edges with Laplacian matrix \( L_G \), then

1. \(-|\mathcal{C}(G)| < \text{perm}(L_G) \leq |\mathcal{C}(G)|\), and \( \text{perm}(L_G) = |\mathcal{C}(G)| \) if, and only if, \( G \) is extroverted or introverted,

2. \(-|\mathcal{C}(G)| < \text{det}(L_G) \leq |\mathcal{C}(G)|\), and \( \text{det}(L_G) = |\mathcal{C}(G)| \) if, and only if, the connected components of \( G \) consist of bouquets of introverted or extroverted \( k \)-edges.

**Proof.** From 4.1.1 it is clear that each of \( \text{perm}(L_G) \) and \( \text{det}(L_G) \) are in the interval \([-|\mathcal{C}(G)|, |\mathcal{C}(G)|]\).

**Proof of 1.** From 4.1.1 \( \text{perm}(L_G) = |\mathcal{C}(G)| \) if, and only if, for every contributor \( c \), \( oc(c) \) and \( nc(c) \) have the same parity. Also, \( \text{perm}(L_G) = -|\mathcal{C}(G)| \) if, and only if, for every contributor \( c \), \( oc(c) \) and \( nc(c) \) have different parity. From Theorem 4.3.1 \( \text{perm}(L_G) = |\mathcal{C}(G)| \) if, and only if, \( G \) is extroverted or introverted. To see \( \text{perm}(L_G) \neq -|\mathcal{C}(G)| \) use a similar refinement argument as in 4.3.1 on the unequal number of \( oc(c) \) and \( nc(c) \).

**Proof of 2.** From 4.1.1 \( \text{det}(L_G) = |\mathcal{C}(G)| \) if, and only if, every contributor has an even number of positive circles, while \( \text{det}(L_G) = -|\mathcal{C}(G)| \) if, and only if, every contributor has an odd number of positive circles. To see that \( \text{det}(L_G) \neq -|\mathcal{C}(G)| \) observe that there is at least one contributor with 0 positive circles, since there is at least one contributor corresponding to the identity permutation.

If the connected components of \( G \) consist of a bouquet of introverted or extroverted \( k \)-edges, there are 0 positive circles, and \( \text{det}(L_G) = |\mathcal{C}(G)| \). To see the converse, observe that if \( G \) contains a non-loop adjacency, then there is a contributor with the resulting degenerate 2-circle as the only circle, and it is necessarily positive. Therefore, the only adjacencies \( G \) can contain are negative loops, and the result follows. \( \square \)
Example 4.3.3. The oriented 3-edge in Figure 2 is extroverted with 6 contributors so \( \text{perm}(L_G) = 6 \).

A refinement argument for adjacency matrices cannot be used on elements of \( \mathcal{C}_{=0}(G) \) as they are necessarily backstep-free. Moreover, for oriented hypergraphs, if a circle of a contributor lies within a single edge of \( G \), then the odd/even parity of the circle determines if it is negative/positive. This presents some complications as these contributor-circles are not circles in the oriented hypergraph. It is easy to see that this prevents balanced oriented hypergraphs from being a class of oriented hypergraphs where \( \text{perm}(A_G) = |\mathcal{C}_{=0}(G)| \) — consider an oriented hypergraph consisting of a 4-edge and a 2-edge that share a single vertex, and the contributor consisting of the degenerate 2-circle for the 2-edge and the 3-circle on the remaining 4-edge vertices. However, the following signed graphic theorem is true:

**Theorem 4.3.4.** If \( G \) is a balanced signed graph, then \( \text{perm}(A_G) \) is maximal and equals \( |\mathcal{C}_{=0}(G)| \).

**Proof.** From Theorem 4.1.1 \( \text{perm}(A_G) = |\mathcal{C}_{=0}(G)| \) if, and only if, every contributor has an even number of negative circles. A balanced signed graph has 0 negative circles, while degenerate 2-circles are positive, so every element of \( \mathcal{C}_{=0}(G) \) has no negative circles. \( \square \)

Balanced signed graphs are not the only class of signed graphs where \( \text{perm}(A_G) = |\mathcal{C}_{=0}(G)| \), as the negative 3-circuit in Figure 3 is maximal, it is easy to check that negative circuit graphs are also optimal.

The determinant of \( A_G \) presents similar issues. However, bouquets of 1-edges and positive 2-edge loops, and positive circuits of length \( \equiv 0 \pmod{4} \), can easily be checked to optimize \( \text{det}(A_G) \).

**Problem 4.3.5.** Characterize the oriented hypergraphs that optimize the \( x^k \) coefficient of a given characteristic polynomial.
