ABSTRACT

Today, generalized linear mixed models (GLMM) are broadly used in many fields. However, the development of tools for performing simultaneous inference has been largely neglected in this domain. A framework for joint inference is indispensable to carry out statistically valid multiple comparisons of parameters of interest between all or several clusters. We therefore develop simultaneous confidence intervals and multiple testing procedures for empirical best predictors under GLMM. In addition, we implement our methodology to study widely employed examples of mixed models, that is, the unit-level binomial, the area-level Poisson-gamma and the area-level Poisson-lognormal mixed models. The asymptotic results are accompanied by extensive simulations. A case study on predicting poverty rates illustrates applicability and advantages of our simultaneous inference tools.

1. Introduction

Generalized linear mixed models (GLMM) are suitable for modeling clustered and correlated data with categorical or count outcomes. They are ubiquitous in applied statistics, for example, in biometrics or small area estimation (SAE). In the latter, they serve to analyze surveys on a disaggregated level. Despite an increasing interest, for example, to guide resource allocation, the development of methods for simultaneous inference for predictors is missing. It is surprising as only those would make joint considerations of clusters valid. Available \((1 – \alpha)\)-confidence intervals (CI) for mixed parameters (except the credibility intervals of Ganesh 2009) are constructed such that for each study at least \(\alpha\) 100% of them do not contain the true value. Undoubtedly, practitioners do compare, but so far without valid statistical tools. We aim to close this distressing gap, not to improve any existing method.

Specifically, we introduce simultaneous confidence interval (SCI) and multiple test procedure (MTP) for the empirical best predictor (EBP) of Jiang (2003). They are based on max-type statistics combined with extreme value theory. We prove asymptotic convergence of SCI and MTP for nested (or hierarchical) GLMM within the exponential family. We study the numerical performance of our SCI and MTP for two area-level and one unit-level mixed models that are widely used, for example, for studying local poverty rates (Pratesi 2016). All introduced methods show a satisfactory performance within considered modeling frameworks. Even though our estimates under the area-level models appear to be less volatile, one can argue that EBPs are not directly comparable because different methods and model classes are used. Finally, under area-level Poisson-gamma model, we derive a new mean squared error (MSE) estimator which is of crucial interest in SAE.

The amount of literature on estimation and testing under GLMM is considerable, see, i.a., the review of Tuerlinckx et al. (2006), the monograph of Jiang (2007), and the article of Ghosh et al. (1998) which is particularly interesting within the context of SAE. Furthermore, researchers put forward several methodologies broadly used in the analysis of count data. Molina, Saei, and Lombardia (2007) and Scealy (2010) studied the estimation of labor force status using multinomial logistic models, whereas Saei and Taylor (2012) focused on the same target parameter, and examined the performance of a bivariate random components model. Chandra, Chambers, and Salvati (2012) and Franco and Bell (2015) provided extensions for modeling proportions using logistic unit- and area-level models. Hobza and Morales (2016) implemented the EBP for unit-level, and Boubeta, Lombardia, and Morales (2016) for area-level GLMM to study poverty in small areas. Chambers, Salvati, and Tzavidis (2012) and Tzavidis et al. (2015) extended the M-quantile inference for robust estimation and prediction of count data. Yet, to the best of our knowledge, no one addresses the issue of simultaneous inference for clusters-level parameters when applying GLMM. Likewise, little research has been carried out on simultaneous inference for cluster level parameters in linear mixed effects models (LMM). Ganesh (2009) developed credibility intervals for a mixed parameter in a particular area-level model. Reluga, Lombardia, and Sperlich (2019) proposed bootstrap SCI and MTP for mixed parameter under LMM, whereas Kramlinger, Krivobokova, and Sperlich (2018) developed a framework for marginal and conditional inference with quadratic forms.
2. Best Prediction for GLMM

Let $D$ be the number of clusters or areas with $d \in [D]$, $n_d$ the number of sampled units in each area $j \in [n_d]$ with $n = \sum_{d=1}^{D} n_d$, $N_d$ the known population sizes with $N = \sum_{d=1}^{D} N_d$, $[A] = \{1, \ldots, A\}$. Since in our context the notion of cluster and area can be used synonymously, we proceed with the latter. Suppose that \{ $v_d : d = 1, \ldots, D$ \} is a set of independent and identically distributed (iid) random effects with unknown variance $\delta^2$, $\delta > 0$, which is often parameterized as $v_d = \delta u_d$ with $u_d \sim N(0,1)$. The target variable $y_dj$ represents the $j$th sample observation from the $d$th area. Furthermore, we consider nested data structures such that $y_dj \neq y_dj'$ for $d \neq d'$. In full generalization, we assume that random variables $Y_dj$, conditionally on a random effect $u_d$, are independent with a probability density function (pdf) from the exponential family $y_dj|u_d \sim \text{Exp.Family}(\theta)$.

$$g_d(y_dj|u_d, \theta) = \exp(\psi^{-1} [y_dj - b(y_dj)] + c(y_dj, \psi)),$$

where $\theta = (\beta^t, \delta, \psi)^t$ with $\delta$ the variability parameter, $\beta = (\beta_1, \ldots, \beta_p)^t$ regression parameters of auxiliary variables $x_dj = (x_{d1j}, \ldots, x_{dpj})^t$ for which typically $x_{d1j} = 1, \forall j \in [n_d]$ $\forall d \in [D]$, and $y_dj, \psi$ are canonical and scale parameters, respectively. Link function $M$ relates $\mathbb{E}(Y_dj|u_d)$ to a linear mixed model such that $y_dj = M(\mathbb{E}(Y_dj|u_d)) = x_dj^t \beta + \delta u_d$.

2.1. Estimation and Computation

Let $y_d = (y_{d1}, \ldots, y_{dD})^t$ for all $d \in [D]$ be the vector of outcomes, and $y = (y_1^t, \ldots, y_D^t)^t$. A conditional pdf of $y$ and the likelihood contribution from each area $d$ are given by

$$L_d(\theta) := f_d(y_d|\theta) = \int g_d(y_d|u_d, \theta)|h(u_d)|du_d$$

$$= \prod_{j=1}^{n_d} g_d(y_dj|u_d, \theta)h(u_d)du_d,$$

where $\theta$ can be derived from

$$\mathcal{L}(\theta) := \prod_{d=1}^{D} L_d(\theta) = \prod_{d=1}^{D} \prod_{j=1}^{n_d} g_d(y_dj|u_d, \theta)h(u_d)du_d.$$ 

In case of area-level models, $n_d = 1$, and Equation (1) simplifies accordingly. For a concise presentation, we assume that there is a single random effect for each area such that the integral in Equation (1) is one-dimensional. Extensions to multidimensional random effects follow immediately with some changes of notations and more complicated computation. Finding an analytical solution to Equation (1) is difficult unless the integral can be simplified. Often one evaluates the integral numerically by Laplace approximation (LA) (De Bruijn 1981), Gaussian quadrature (GQ) (Naylor and Smith 1982) or adaptive GQ (AGQ) (Pinheiro and Bates 1995). In what follows, we proceed with AGQ as it is a higher order version of LA, that is, it gives smaller approximation errors (Bianconcini 2014). An alternative is the quasi-likelihood (Breslow and Clayton 1993) which suffers from a nondecreasing bias (Tuerlinckx et al. 2006), and the method of moments (Jiang 1998). In addition, researchers considerably advanced in developing methods to compute maximum likelihood (ML) estimators under GLMM. (Jiang 2007, sec. 4.1) proposed an expectation–maximization algorithm, whereas Lele, Nadeem, and Schmuland (2010) developed the so-called data cloning subsequently implemented by Torabi (2012).

Since we consider a prediction problem of possibly nonlinear mixed effects $\zeta_d = \gamma_d(\beta, u_d)$, we use the best predictor (BP) $\tilde{\zeta}_d$ in the sense of minimizing the area-specific MSE in Equation (3) which is actually the area-specific mean square prediction error:

$$\tilde{\zeta}_d = \tilde{\zeta}_d(\theta) := E(\gamma_d(\beta, u_d)|y) = E(\gamma_d(\beta, u_d)|y_d)$$

$$= \frac{\int \gamma_d(\beta, u_d)g_d(y_d|u_d, \theta)|h(u_d)|du_d}{\int g_d(y_d|u_d, \theta)|h(u_d)|du_d}. \quad (2)$$

Simplification of Equation (2) is possible by choosing the pdf of $u_d$ accordingly. If we replace $\theta$ by a consistent estimator, then we obtain EBP $\hat{\zeta}_d =:\hat{P}(\theta)$. Note that in order to obtain the consistency for random effects, one needs to assume that $n_d \to \infty$ for each $\zeta_d$, $d = 1, \ldots, D$ (Jiang and Lahiri 2001).

Regarding the estimation of the variability of the EBP $\tilde{\zeta}_d$, MSE is by far the most popular measure. Well known techniques to estimate MSE are the analytical approximation based on a Taylor expansion (Jiang 2003), and parametric bootstrap approaches (Boubeta, Lombardía, and Morales 2016; Hobza and Morales 2016). Consider the following MSE decomposition:

$$\text{MSE}(\tilde{\zeta}_d) = E[(\tilde{\zeta}_d(\theta) - \zeta)^2] = E[(\hat{\zeta}_d(\theta) - \tilde{\zeta}_d(\theta))^2] + E[(\tilde{\zeta}_d(\theta) - \zeta)^2]$$

$$=: \mathcal{G}_d + \mathcal{G}_d^l, \quad (3)$$

which can be derived applying the law of iterated expectations (for details, see Jiang 2003, and our SM). The analytical formulas of MSE estimators are model dependent. Bootstrapping permits to obtain estimators that do not vary with the model assumed. In what follows, we denote with $\mathbb{E}^*$, $\mathbb{V}^*$, and $\text{MSE}^*$, the corresponding bootstrap operators for expected value, variance and MSE and define

$$\text{MSE}^*_B(\tilde{\zeta}_d) = \mathbb{E}^*(\hat{\zeta}_d - \zeta)^2$$

$$\approx B^{-1}_1 \sum_{b_1=1}^{B_1} (\hat{\zeta}_d^{b_1} - \zeta)^2 =: \text{MSE}^*_B(\tilde{\zeta}_d), \quad (4)$$

which is a bootstrap equivalent of Equation (3). In their article, Hall and Maiti (2006) pointed out that (4) tends to underestimate the MSE, and propose a double-bootstrap bias-correction

$$\text{MSE}^*_B(\tilde{\zeta}_d) = 2 \text{MSE}^*_B(\hat{\zeta}_d) - \text{MSE}^*_B(\tilde{\zeta}_d)$$

$$\approx 2 \text{MSE}^*_B(\hat{\zeta}_d) - \text{MSE}^*_B(\tilde{\zeta}_d), \quad (5)$$
where \( \text{MSE}_{B_2}^* (\hat{\zeta}_d) \) is the second-stage bootstrap MSE estimator, that is
\[
\text{MSE}_{B_2}^* (\hat{\zeta}_d) = E^{ss}\left\{ (\hat{\zeta}_d^{ss} - \zeta_d^{ss})^2 \right\}
\approx B_1^{-1} B_2^{-1} \sum_{b_1=1}^{B_1} \sum_{b_2=1}^{B_2} \left( \hat{\zeta}_d^{ss(b_1,b_2)} - \zeta_d^{ss(b_1,b_2)} \right)^2
=: \text{mse}_{B_2}(\hat{\zeta}_d).
\]
The computation of \( \text{MSE}_{B_2}^* (\hat{\zeta}_d) \) involves selecting \( B_2 \) bootstrap replicates from each first-stage bootstrap sample. In this article we do not aim for a precise estimation of the variability of EBP, but the construction of narrow SCI and reliable MTPs. It turns out that for doing this, the use of an estimate of \( g_{1d} \) as in Equation (3) yields better results than using an estimate of the entire MSE (see Section 4), similarly as in Chatterjee, Lahiri, and Li (2008) under LMM.

### 2.2. Popular Examples of GLMM and Their Properties

#### 2.2.1. Poisson-Gamma Area-Level Model

The Poisson-gamma model is widely applied for modeling counts in the presence of overdispersion (see Cameron and Trivedi 2013, Section 4.2.2.). Within the SAE context, Chen, Jiang, and Nguyen (2015) investigated the observed best prediction and bootstrap MSE estimation for small area means counts. Among others, they also consider a Poisson-gamma specification. We propose a different model formulation, focus on the EBP of \( \hat{\zeta}_d \) and develop a plug-in MSE estimator. Let \( y_d|u_d \sim \text{Pois}(\mu_{d}^{PG}) \), \( d = 1, \ldots, D \), where \( \mu_{d}^{PG} > 0 \), \( n_d = 1 \forall d \in [D] \), with canonical parameter \( \log \mu_{d}^{PG} = x_d^\beta \) and \( w_d := \exp(u_d) \sim \Gamma(\delta, \delta) \). Then, \( \text{E}(y_d|u_d) = \mu_{d}^{PG} = \lambda_d w_d = \exp(x_d^\beta w_d) = \exp(x_d^\beta + u_d) \). Since Gamma pdf is conjugate to the Poisson, their mixture yields a negative binomial \( y_d \sim \text{NB}(\lambda_d, \delta^{-1}) \) with likelihood
\[
\mathcal{L}^{PG} (\theta) := f^{PG} (y|\theta) = \prod_{d=1}^{D} \frac{\Gamma(y_d + \delta)}{(y_d + 1)^{\lambda_d} \Gamma(\delta)} \left( \frac{\delta}{\lambda_d + \delta} \right)^{y_d} \left( \frac{\lambda_d}{\delta} \right)^{\lambda_d},
\]
where \( \text{E}(y_d) = \lambda_d \) and \( \text{Var}(y_d) = \lambda_d + \delta^{-1} \lambda_d^2 \). The marginal mean of \( y_d \) is the same as in the Poisson case, but the random effect increases the variance. Suppose that this model holds for all areas of population \( P \) of size \( N \) partitioned into subpopulations \( P_1, P_2, \ldots, P_D \) of sizes \( N_1, N_2, \ldots, N_D \). We can show that the BP for counts \( \mu_{d}^{PG} (\theta) := \mathbb{E}(\mu_{d}^{PG} | y_d) \) is
\[
\mathbb{E}(\mu_{d}^{PG} | y_d) = \int_{0}^{\infty} \exp(-\lambda_d w_d) \frac{w_d^{y_d}}{\Gamma(y_d + 1)} \frac{\lambda_d}{\Gamma(\delta)} \frac{\delta}{\lambda_d + \delta} \left( \frac{\lambda_d}{\delta} \right)^{\lambda_d} w_d \, dw_d
= \frac{\lambda_d y_d + \delta}{\lambda_d + \delta}
=: \psi_d^{PG} (y_d, \theta).
\]
Once θ is estimated, we obtain BPs \( \hat{\mu}_d^{PL} \), \( \tilde{\rho}_d \), and EBPs \( \tilde{\mu}_d \), \( \tilde{\rho}_d \) using the formulas from Boubeta, Lombardía, and Morales (2016). In Section 4.1 we estimate their MSE by bootstrap.

### 2.2.3. Logit Unit-Level Model

The unit-level logit model is a popular choice for binary responses, comprehensively discussed by Hobza and Morales (2016). Under this setting, \( y_{dj} | u_d \sim \text{Bin}(m_{dj}, p_{dj}) \), \( u_d \sim N(0, 1) \) with \( m_{dj} \) a known size parameter for a logistic regression. The natural parameter is \( p_{dj} / (1 - p_{dj}) = x_{dj} \beta + \delta u_d \), \( d \in [D], \) \( j \in [n_d] \) where \( p_{dj} = \exp(x_{dj} \beta + \delta u_d) / (1 + \exp(x_{dj} \beta + \delta u_d)) \).

We assume that the unit-level logit model holds for all units of population \( P \) of size \( N \), partitioned into \( D \) subpopulations \( P_d \) of sizes \( N_d, \) \( d \in [D] \). Let \( \zeta_d = \mu_d^U = \sum_{j=1}^{N_d} p_{dj} \). As for the Poisson models, we have \( \varphi = 1 \) and therefore \( \theta = (\beta^t, \delta) \).

The likelihood is given by

\[
L_U(\theta) := f_U(y_j | \beta, \delta) = (2\pi)^{-D/2} \prod_{d=1}^{D} \int_{\mathbb{R}} \prod_{j=1}^{n_d} \log \left( m_{dj} \right) + \sum_{j=1}^{n_d} y_{dj}(x_{dj} \beta + \delta u_d) \right) \prod_{j=1}^{n_d} (1 + \exp(x_{dj} \beta + \delta u_d)) du_d.
\]

We can proceed with the estimation of the BP \( \tilde{\mu}_d(\theta) \) and \( \tilde{\mu}_d^U = \sum_{j=1}^{N_d} p_{dj} \) only if we have access to the information on each population unit. In practice, however, the auxiliary information is available only for the sample units. Then, following the suggestion of Hobza and Morales (2016), we can still estimate the population quantity of interest by using only categorical covariates. Suppose that they take a finite number of values \( x_{dj} \in \{z_1, \ldots, z_L\} \) for \( d \in [D] \) and \( j \in [n_d] \) with \( z_l \) denoting the resulting covariate class. We then define

\[
\tilde{\mu}_d = \frac{\mu_d^U}{N_d}, \quad \tilde{\mu}_d^U = \sum_{j=1}^{N_d} p_{dj} = \sum_{l=1}^{L} N_{dl} r_{dl}, \quad \text{with}
\]

where \( N_{dl} = \#\{l \in P_d : x_{dj} = z_l\} \) is the known size of class \( z_l \) in area \( d \). Hobza and Morales (2016) derived BP \( \tilde{\mu}_d^U(\theta) \) and EBP \( \tilde{\mu}_d(\theta) \) for \( \mu_d^U \) as well as for other quantities in Equation (11).

Due to the computational burden of the analytical estimator, in Section 4.2 we use bootstrap for obtaining an estimate of MSE.

### 3. Simultaneous Intervals and Multiple Testing

To construct CI for \( \zeta_d \) that account for the effect of estimates from other areas, we need to find a region \( \mathcal{T}_{1-\alpha} \) such that \( P(\zeta_d \in \mathcal{T}_{1-\alpha}) = 1 - \alpha \). Define

\[
S_0 = \max_{d=1, \ldots, D} |S_{0d}|, \quad \text{with} \quad S_{0d} = \frac{\tilde{\zeta}_d - \zeta_d}{\hat{\sigma}(\zeta_d)}, \quad \forall d \in [D],
\]

\[
q_{S_0}^{(1-\alpha)} = \inf \{ t \in \mathbb{R} : P(S_0 \leq t) \geq 1 - \alpha \},
\]

with \( \hat{\sigma}(\zeta_d) \) being an estimate of the variability of EBP \( \hat{\zeta}_d \). We then consider

\[
\alpha = P \left( \frac{\hat{\zeta}_d - \zeta_d}{\hat{\sigma}(\zeta_d)} > q_{S_0}^{(1-\alpha)} \hat{\sigma}(\zeta_d) \text{ for some } d \in [D] \right)
\]

\[
= P \left( \max_{d=1, \ldots, D} \left| \frac{\hat{\zeta}_d - \zeta_d}{\hat{\sigma}(\zeta_d)} \right| > q_{S_0}^{(1-\alpha)} \right).
\]

Constructing SCI boils down to the estimation of \( q_{S_0}^{(1-\alpha)} \), as one can define then

\[
\mathcal{T}_{d,1-\alpha}^S = \prod_{d=1}^{D} \mathcal{T}_{d,1-\alpha}^S, \quad \text{with} \quad \mathcal{T}_{d,1-\alpha}^S = \left\{ \hat{\zeta}_d \pm q_{S_0}^{(1-\alpha)} \times \hat{\sigma}(\zeta_d) \right\},
\]

(15)

where \( \times \) denotes a generalized Cartesian product. \( \mathcal{T}_{d,1-\alpha}^S \) covers all \( \zeta_d \) with probability \( 1 - \alpha \), that is, its joint confidence level is \( 1 - \alpha \). In contrast, for each \( q_{S_0}^{(1-\alpha)} \) defined analogously to \( q_{S_0}^{(1-\alpha)} \), with \( S_0 \) replaced by \( |S_{0d}| \), individual area CI (IC) are given by

\[
\mathcal{T}_{d,1-\alpha}^{CI} = \left\{ \hat{\zeta}_d \pm q_{S_0}^{(1-\alpha)} \times \hat{\sigma}(\zeta_d) \right\} \forall d \in [D].
\]

By construction, CI does not contain \( \zeta_d \) for at least 100% of all areas.

**Remark.** \( \mathcal{T}_{d,1-\alpha}^{CI} \) is designed to cover \( \zeta_d \) at an individual confidence level. Consequently, the joint coverage probability of ICIs decreases in a cumulative way for increasing \( D \). This highlights the need to construct SCI. Nevertheless, maintaining \( 1 - \alpha \) simultaneous confidence levels of SCI \( \mathcal{T}_{d,1-\alpha}^S \) makes its constituents \( \mathcal{T}_{d,1-\alpha}^S \) wider than corresponding ICIs \( \mathcal{T}_{d,1-\alpha}^{CI} \). This is not surprising because \( \mathcal{T}_{d,1-\alpha}^S \) and \( \mathcal{T}_{d,1-\alpha}^{CI} \) were constructed to cover different sets which serve distinct inferential purposes. It is worth mentioning that the length of \( \mathcal{T}_{d,1-\alpha}^S \) stabilizes as for growing \( D \) we observe two opposite trends: the increase of area parameters to cover and the decrease of MSE (see Tables 1 and 3).

The SCI defined in Equation (15) is not operational as the distribution of \( S_0 \) is unknown. The problem can be circumvented by bootstrap approximation: for \( b_1, \ldots, B_1 \) set

\[
S_{B}^{(b_1)} = \max_{d=1, \ldots, D} |S_{0d}^{(b_1)}|, \quad S_{0d}^{(b_1)} = \frac{\hat{\zeta}_d^{(b_1)} - \zeta_d^{(b_1)}}{\hat{\sigma}(\zeta_d^{(b_1)})} \binom{S_{0d}^{(b_1)}}{\zeta_d^{(b_1)}},
\]

(17)

and approximate the critical value \( d_{(1-\alpha)} \) of \( S_{B}^{(b_1)} \) by \( \{1 - \alpha\} B_1 + 1 \)th-order statistic of the \( S_{B}^{(b_1)} \). Then the bootstrap equivalent of Equation (15) is

\[
\mathcal{T}_{d,1-\alpha}^{B} = \prod_{d=1}^{B} \mathcal{T}_{d,1-\alpha}^{B}, \quad \text{where} \quad \mathcal{T}_{d,1-\alpha}^{B} = \left\{ \hat{\zeta}_d \pm q_{S_0}^{(1-\alpha)} \times \hat{\sigma}(\zeta_d) \right\}.
\]

(18)

An alternative approach to Equation (12) could be to take computationally simpler nonstudentized statistics. Yet, already DiCiccio and Efron (1996) pointed out that the lack of studentization results in slower convergence rates. Since the application of nonstudentized SCI did not yield satisfactory results, we decided not to include them.
Our methodology is also applicable for hypothesis testing. Consider the test problem

\[ H_0 : B\boldsymbol{\xi} = b \quad \text{vs.} \quad H_1 : B\boldsymbol{\xi} \neq b, \tag{19} \]

where \( B \in \mathbb{R}^{D' \times D} \), \( D' \leq D, b \in \mathbb{R}^D \). We are interested in max-type statistic \( t_H \) such that

\[
\begin{align*}
    t_H &= \max_{d=1,\ldots,D'} |t_{Hd}|, \\
    t_{Hd} &= \frac{\hat{\xi}_d^H - b_d}{\hat{\sigma}(\hat{\xi}_d^H)}, \\
    S_{H0} &= \max_{d=1,\ldots,D'} |S_{H0d}|, \quad S_{H0d} = \frac{\hat{\xi}_d^H - \xi^H}{\hat{\sigma}(\hat{\xi}_d^H)},
\end{align*}
\]

where \( \xi^H = (\xi_1^H, \ldots, \xi_{D'}^H)' = B\boldsymbol{\xi} \in \mathbb{R}^{D'} \) with \( \hat{\xi}^H \) being its estimator. One rejects \( H_0 \) at the \( \alpha \)-level if \( t_{Hd} \geq q_{H0}(1-\alpha) \) with \( q_{H0}(1-\alpha) = \inf\{t \in \mathbb{R} : P(S_{H0} \leq t) \geq 1 - \alpha \} \).

In practice, we might use such a test to examine differences between area characteristics. Similarly as for SCI, we approximate \( q_{H0}(1-\alpha) \) using bootstrap to a modified version of statistic \( S_0 \), namely

\[ q_{BH0}^{(1-\alpha)} = \inf\{t \in \mathbb{R} : P(S_{BH0} \leq t \mid y, X) \geq 1 - \alpha \}, \tag{21} \]

where \( S_{BH0} \) in the \( \hat{\xi}_1^H \) bootstrap sample is

\[ \hat{\xi}^{(b)}_{BH0} = \max_{d=1,\ldots,D'} |\hat{\xi}^{(b)}_{H0d}|, \quad \hat{\xi}^{(b)}_{BH0d} = \frac{\hat{\xi}^{H(b)}_d - \xi^{H(b)}_d}{\hat{\sigma}(\hat{\xi}^{H(b)}_d)}, \tag{22} \]

with \( \hat{\xi}^{H(b)}_d = (\hat{\xi}_1^{H(b)}_1, \ldots, \hat{\xi}_D^{H(b)}_d)' = B\boldsymbol{\xi}^{(b)} \in \mathbb{R}^D \) and \( \xi^{H(b)}_d = (\xi_1^{H(b)}_1, \ldots, \xi_D^{H(b)}_d)' \) its corresponding estimated version.

We provide the consistency of our bootstrap-based CI and tests, as well as asymptotic convergence and coverage probability. Proofs are deferred to Appendix A.2 and A.3. Suppose that \( \hat{\theta} \) is consistent such that \(|\hat{\theta} - \theta| = O_P(n^{-c}), c > 0 \). Since for the GLMM with clustered random effects the log-likelihood can be expressed as the sum of independent random components, the consistency of \( \hat{\theta} \) estimated by ML follows assuming a classical theory. The consistency under a general GLMM had been an open problem for many years until it was solved by Jiang (2013). Bianconcini (2014) and Huber, Ronchetti, and Victoria-Feser (2004) investigated the consistency of \( \hat{\theta} \) once we compute it using AGQ and LA respectively. For our purpose, we need to prove the bootstrap consistency.
1–5 from Appendix A.1 it holds that
\[
\sup_{w \in \mathbb{R}} |T_D(w) - T_D^a(w)| = o_P(1).
\]

**Corollary 1.** Proposition 3 implies that under the same assumptions,
\[
P(\hat{\zeta}_d \in I_{1-\alpha}^B \forall d \in [D]) \to 1 - \alpha.
\]

Since we use almost identical max-type statistics in Equations (12) and (20), the construction of MTP follows almost immediately from the correspondence between tests and CI. In fact, the acceptance region of our test is \( T_{1-\alpha}^H = X_d = T_{1-\alpha}^H \), where
\[
I_{1-\alpha}^H = \left\{ \hat{\zeta}_d - q_{\delta_0}^{(1-\alpha)} \times \hat{\delta}(\hat{\zeta}_d) \leq b_d \leq \hat{\zeta}_d + q_{\delta_0}^{(1-\alpha)} \times \hat{\delta}(\hat{\zeta}_d) \right\},
\]
that is, we reject \( H_0 \) if \( b \notin I_{1-\alpha}^H \). We can write \( P(\hat{h}_d \in I_{1-\alpha}^H \forall d \in [D]) = 1 - \alpha \). Since this probability statement is true for any \( h_d = \zeta_d \), we obtain the CI defined in Equation (15) by inverting the test.

**Corollary 2.** Let \( H_0 \) be the null hypothesis defined in Equation (19) and \( a \in (0, 1) \). Under Proposition 3, we have
\[
P(t_H > q_{B_{1-\alpha}}) \leq \alpha + o(1).
\]

**Remark 2.** Our single-step testing procedure in Equation (19) with a bootstrap critical value in Equation (21) controls weakly for the family-wise error rate (FWER), and might be limited in detecting false null hypotheses once we deal with a large D. Yet, we can readily extend our test to a bootstrap-based step-down procedure of Romano, Shaikh, and Wolf (2008) which controls the false discovery rate with a better power to detect false \( H_{0d} \) than FWER.

### 4. Empirical Reliability Study

We performed intensive simulation studies to assess the reliability of our methods. SCI and MTP for EBP were constructed with different estimators of variability under the models presented in Sections 2.2.1–2.2.3. First, we examined the relative bias and relative root-MSE of fixed effects \( \hat{\beta} \) and variability parameter \( \hat{\delta} \). Then, the performance of EBP was evaluated comparing bias, average absolute bias and MSE for \( D = 26, 52, \) and 78. Since they did not show any atypical pattern, the results under Poisson area-level models and logistic unit-level model were deferred to the SM. Regarding SCIs, we calculated empirical coverage probability (ECP), average interval width (AIW), and the AIW variation (AIWV):

- ECP: \( \left\{ \hat{\zeta}_d^{(k)} \in I_{1-\alpha}^\delta \forall d \in [D] \right\} \)
- AIW: \( \frac{1}{DK} \sum_{d=1}^{D} \sum_{k=1}^{K} (\omega_d^{(k)} - \bar{\omega}_d) \)
- AIWV: \( \frac{1}{D(K-1)} \sum_{d=1}^{D} \sum_{k=1}^{K} (\omega_d^{(k)} - \bar{\omega}_d)^2 \)
- \( \bar{\omega}_d = \frac{1}{K} \sum_{k=1}^{K} \omega_d^{(k)} \), \( d = 1 \ldots, D \).

For each simulation run \( k \) we record the widths of the SCI and check whether they cover all EBPs. ECP is then computed by averaging over \( K \) simulation runs and is aimed to be close to \( 1 - \alpha \). AIW is obtained by averaging over the simulation runs and areas. Narrower intervals are preferable if its ECP is close to the nominal level. These are standard measures to assess the quality of interval estimators (Chatterjee, Lahiri, and Li 2008; Ganesh 2009). Lower AIWV values indicate that the length is stable and does not depend on the simulation run.

#### 4.1. Finite Sample Performance Under Area-Level Models

Under the Poisson-gamma model we set \( y_{d} \sim \text{Poisson}(\mu_{PL}^d) \), \( \mu_{PL}^d = \lambda_d w_d \). Covariates, parameters and sample sizes are taken from our case study in Section 5, that is, we set \( \theta = (\beta^1, \delta) = (10.038, 7.747, -3.136, 11.317, -2.466, 2.480)^\top \) and \( D = [26, 52, 78], n_d = 1, \forall d \in [D], n = D \). For \( D = 52 \) we take covariates from the original sample, for \( D = 26 \) we randomly select the areas using simple random sampling without replacement, and for \( D = 78 \), we take the original sample plus 26 randomly selected areas, that is, these areas enter at most twice. Parameter of interest is the area proportion of individuals below the poverty line, \( \hat{\mu}_{PL}^d = \hat{\mu}_{PL}^d / n_d \). The EBP for \( \hat{\mu}_{PL}^d \) is given in Equation (7). Since \( N_d \) is usually unknown, in practice it is replaced by its estimate, see Equation (25) in Section 5. We apply double bootstrap with \( B_1 = 1000 \) first-stage and \( B_2 = 1 \) second-stage bootstrap replicates (the choice of the latter is motivated by Erciulescu and Fuller 2014). We generate \( K = 1000 \) samples with the same areas and fixed covariates, but randomly drawn \( w_d \) and \( y_d \). SCIs and ICs are constructed as follows:

1. Fit the model to the data and obtain estimates \( \hat{\theta} = (\hat{\beta}, \hat{\delta}) \).
2. For \( b_1 = 1 \ldots, B_1 \) bootstrap samples, generate \( w_{a(b_1)} \sim \text{Gamma}(\hat{\delta}(\hat{\theta}) \hat{\delta}) \) iid and set \( \mu_{PL}^d = \hat{\lambda}_d w_{a(b_1)} \) and \( y_{a(b_1)} \sim \text{Poisson}(\mu_{PL}^d) \).
3. For each bootstrap sample calculate \( \mu_{PL}^d \), \( \hat{\mu}_{PL}^d \), \( \hat{\delta}(\hat{\theta}) \) and \( \hat{\delta}(\theta)(\theta) \), \( AD_{PG}^{(b_1)} = |\hat{\mu}_{PL}^d - \mu_{PL}^d| \).
   (a) For \( b_2 = 1 \ldots, B_2 \) generate samples \( w_{a(b_1, b_2)} \sim \text{Gamma}(\hat{\delta}(\hat{\theta}) \hat{\delta}(\hat{\theta})) \) iid and
   \( \mu_{PL}^d = \hat{\mu}_{PL}^d + \delta_{(b_1, b_2)} \), \( y_{a(b_1, b_2)} \sim \text{Poisson}(\mu_{PL}^d) \).
   (b) For each bootstrap sample calculate \( \mu_{PL}^d \) and \( \hat{\mu}_{PL}^d \).
   (c) Set \( \text{mse}_{a(b_1)} = \frac{1}{B_2} \sum_{b_2=1}^{B_2} \left( \hat{\mu}_{PL}^d - \mu_{PL}^d \right)^2 \).
4. Calculate bootstrap estimates \( \hat{\delta}(\hat{\theta}) \) as in Equation (9) as well as
   \( \text{mse}_{b_1} = \frac{1}{B_1} \sum_{b_1=1}^{B_1} \left( \hat{\mu}_{PL}^d - \mu_{PL}^d \right)^2 \),
   \( \text{mse}_{BC}(\hat{\mu}_{PL}^d) = 2\text{mse}_{b_1}(\hat{\mu}_{PL}^d) - \frac{1}{B_1} \sum_{b_1=1}^{B_1} \text{mse}_{a(b_1)} \).
5. Calculate statistic \( S_{\text{PG},B} \) with the critical value \( q_{\text{PG},B}^{(1-\alpha)} \) obtained from the bootstrap sample \( S_{\text{PG},B} = (S_{\text{PG},B}^{(1)}, \ldots, S_{\text{PG},B}^{(B)})' \), where

\[
S_{\text{PG},B}^{(b)} = \max_{d=1,\ldots,D} AD_{\text{PG},d} / \hat{q}_{\text{PG},b}^{*} \quad \text{and} \quad \hat{q}_{\text{PG},B}^{(1-\alpha)} = Q_{1-\alpha}(S_{\text{PG},B})
\]
as well as a variance estimate for \( \hat{\theta} \):

\[
\text{var}(\hat{\theta}) = B \sum_{b=1}^{B} (\hat{\theta}^{(b)} - \bar{\theta}) (\hat{\theta}^{(b)} - \bar{\theta})'
\]

\[\hat{\theta} = \frac{1}{B} \sum_{b=1}^{B} \hat{\theta}^{(b)} . \tag{24}\]

We compare the performance of SCI and MTP for different variability estimates \( \hat{\sigma}(\hat{\mu}_{d}^{\text{PG}}) \) and their bootstrap equivalents \( \hat{\sigma}^{*}(\hat{\mu}_{d}^{\text{PG}}) \), namely for \( \hat{\sigma}(\hat{\mu}_{d}^{\text{PG}}) = \sqrt{\text{mse}_{\text{PG}}(\hat{\mu}_{d}^{\text{PG}})} \) and \( \hat{\sigma}(\hat{\mu}_{d}^{\text{PG}}) = \sqrt{\text{mse}_{\text{PG}}(\hat{\mu}_{d}^{\text{PG}})} \). Here, \( \text{mse}_{\text{PG}} \) refers to either the plug-in mse\(_{P}\), the mse\(_{B}\) or the mse\(_{BC}\), defined in Equations (8), (4), and (5). Steps 3(a)–(c) of the algorithm refer to the second-stage bootstrap which is only necessary to obtain bias-corrected mse\(_{BC}\). Under the Poisson-gamma model, we are interested in the estimation of poverty rates. We thus consider \( \hat{\mu}_{d}^{\text{PG}} = \hat{\mu}_{d}^{\text{PG}} / N_{d} \), \( \hat{\mu}_{d}^{\text{PG}} = \hat{\mu}_{d}^{\text{PG}} / N_{d}^{2} \) and \( \text{mse}_{\text{PG}}(\hat{\mu}_{d}^{\text{PG}}) = \text{mse}_{\text{PG}}(\hat{\mu}_{d}^{\text{PG}}) / N_{d}^{2} \).

For the Poisson-lognormal model with \( y_{dj} \sim \text{Poisson}(\mu_{d}^{\text{PL}}) \), \( \mu_{d}^{\text{PL}} = \nu_{d} \rho_{d} \), the parameter of interest is \( \rho_{d} \) with \( N_{d} = \nu_{d} \) estimated by EBP derived by Boubeta, Lombardia, and Morales (2016). We take the fixed parameters from Section 5, that is, \( (\beta^{'}, \delta) = (-2.264, 3.480, -0.870, 4.842, 0.125, 0.322)' \). Covariates, sample sizes, number of simulation runs and bootstrap replicates are the same as in the case of the Poisson-gamma model. The variability of \( \hat{\rho}_{d} \) was estimated using bootstrap MSEs, that is, mse\(_{B}\) and mse\(_{BC}\). To obtain estimates of SCI and iCI one can use almost the same algorithm as above by changing the way we generate \( y_{dj}^{(b)} \).

Table 1 summarizes the performance of 95% SCI for \( \hat{\mu}_{d}^{\text{PG}} \) constructed with mse\(_{B}\) (B), mse\(_{BC}\) (BC), plug-in mse\(_{P}\) (P) and \( \hat{\mu}_{d}^{\text{PG}} \) (G). For \( \hat{\rho}_{d} \), they were constructed using mse\(_{B}\) (B) and mse\(_{BC}\) (BC). All methods perform very well regarding the coverage ECP, even for \( D = 26 \). In contrast, SCIs constructed using a Bonferroni procedure yield unacceptably low ECP. For instance, for \( D = 52 \) and mse\(_{B}\) it equals 78% for the Poisson-gamma, and 88% for the Poisson-lognormal model. Therefore, we do not further report them.

Figure 1 presents 95% SCI and iCI estimates for a randomly selected simulation under the Poisson-gamma model. The plot is divided into five panels according to the number of units \( N_{d} \) defined in Equation (25) with the first presenting the results for the areas with the fewest observations. The black and red dots represent the true proportions known in a simulation. The color red indicates true parameters known not to be covered by their iCIs. In Figure 1, that holds for four of the true values (\( \approx 7.7% \)). This illustrates well the difference between individual and simultaneous inference as well as a particular relevance of the latter. We obtain similar figures for other simulations (see our SM).

Finally, we studied the performance of our test (19) under Poisson-gamma and Poisson-lognormal models. Results for the latter are in our SM as they reveal the same features. Consider \( H_{0} : \hat{\mu}_{\text{PG}} = b \) vs. \( H_{1} : \hat{\mu}_{\text{PG}} = b + 1.0 \Delta, \) where \( b = \hat{\mu} \) for the same data-generating processes as before. Critical values are obtained from the bootstrap analogues of \( S_{H_{0}} \) calculated similarly as in Step 5 of the algorithm above. Figure 2 shows the power functions of our test based on different variability estimates. They are visibly indistinguishable, which is not surprising given the similar ECPs and A1Ws in Table 1. For \( D = 52 \), that is, the sample size of the real data, the nominal level of 5% is attained almost exactly under \( H_{0} \).

4.2. Finite Sample Performance Under the Unit-Level Model

Under the unit-level model we assume \( y_{dij} \sim \text{Bin}(m_{dij}, p_{dij}) \) with \( p_{dij} = [\exp(x'_{dij} \beta + \delta u_{dij})] / [1 + \exp(x'_{dij} \beta + \delta u_{dij})] \), \( m_{dij} = 1 \), \( u_{dij} \sim N(0,1) \). In our context, \( y_{dij} \) is binary and value 1 indicates an individual below the poverty threshold defined in Section 5. The regression parameters are taken from our case study: \( \theta = (\beta^{'}, \delta) = (-2.048, 0.989, 0.172, 0.760, 0.100, 0.348)' \). Four categorical covariates result in 16 covariate classes \( x_{dij} \in \{z_{1}, \ldots, z_{16}\} \) for which we need to estimate \( N_{d} \) using Equation (25), \( l = 1, \ldots, 16 \). We considered \( D = (26, 52, 78) \) containing unit-level information with \( n = \{11423, 23628, 35818\} \), respectively. Summary statistics for all samples are presented in Table 2. Furthermore, for \( D = 52 \), \( n_{d}, N_{d}, x_{dij}, z_{i} \) are the same as in our case study. The areas for \( D = (26, 78) \) were selected in the same way as in Section 4.1. In addition, for \( D = 78 \), within each of the additional area we sampled with replacement \( n_{d} \) units (i.e., 26 newly sampled areas contained different units in comparison to the original sample). The parameter of interest is the area poverty proportion \( \hat{\mu}_{d}^{'U} \) defined in Equation (11). Given that the original sample size was \( n = 23,628 \), under the unit-level model we restrict our simulations to \( K = 200, B_{1} = 500, \) and \( B_{2} = 1 \). As far as the algorithm for constructing SCI and iCI is concerned, it follows almost the same steps as in Section 4.1. The exact algorithm can be found in the SM.

Table 3 presents the performance of SCI constructed using mse\(_{B}\) (B) and mse\(_{BC}\) (BC). The coverage probability is somewhat lower than the nominal level. In addition, it slightly decreases with increasing \( D \), whereas the AiW increase stabilizes as expected (see Remark 1). The undercoverage might be related to the simulation design. Even though the latter is popular in SAE, it is suboptimal for random effects from the asymptotic point of view (\( n_{d} \rightarrow \infty, d \in [D] \), recall Section 2.1). The results in Table 3 do not demonstrate any inconsistencies with respect to the theoretical developments, nor they exhibit unexpected findings. Due to their limited impact, the equivalents of Figures 1 and 2 for this simulation are deferred to our SM. In comparison to the area-level models, the coverage probability is worse and the average width of SCIs is much larger (it is also the case for the iCI, see our SM). Moreover, fitting unit-level models is computationally more expensive. In our case the estimation of MSE and construction of intervals took about 900–1000 times longer. Since the data-generation processes are different, the numerical results in our simulations
Figure 1. 95% iCI and SCI for proportions with $D = 52$. Red dots indicate true parameters outside iCI, whereas black dots indicate true parameters inside their iCI.

Figure 2. Simulated powers for multiple test $H_0 : \bar{\mu}^P_G = b$ versus $H_1 : \bar{\mu}^P_G = b + 1_{D} \Delta$ under the area-level Poisson-gamma model; (left) $D = 26$, (middle) $D = 52$, (right) $D = 78$.

Table 2. Summary statistics of $n_d$ under different scenarios in the simulation study under the unit-level model.

| $D$ | Min. | Q1 | Q2 | Mean | Q3 | Max. | $D$ | Min. | Q1 | Q2 | Mean | Q3 | Max. | $D$ | Min. | Q1 | Q2 | Mean | Q3 | Max. |
|-----|------|----|----|------|----|------|-----|------|----|----|------|----|------|-----|------|----|----|------|----|------|

Table 3. ECP, AIW and AIW of 95% SCI under the unit-level model.

| $D$ | ECP (in %) | AIW $\times 10^3$ (AIW $\times 10^3$) |
|-----|------------|-------------------------------------|
| 26  | 94.0       | 134.0 (0.193) 135.0 (0.268)          |
| 52  | 93.5       | 150.3 (0.139) 150.9 (0.189)          |
| 78  | 92.0       | 153.9 (0.125) 155.1 (0.234)          |

NOTE: Nominal coverage: 95%.

are not directly comparable. However, our empirical studies suggest to give some preference to the area-level modeling in the considered GLMM settings.

Our simulations lead us to following conclusions. First, for a given sample size and data, our SCI attains the nominal coverage probability, almost independently from the choice of the estimator of variability. In particular, the area-level models yield very accurate results even for small samples. Second, the distinction between SCI and iCI is crucial, and the latter should not be employed in comparative studies. Third, the numerical performance of our test for comparative studies is satisfying. Given the simplicity of SCI and tests based on $\sqrt{g_{1d}}$, we restrict further presentations to them.

Remark 3. In our simulation study, we do not analyze the performance of direct estimators for proportions, because our goal is to study the numerical performance of our MTP and SCIs, and to compare them to existing iCIs. Since MTP and SCI are the first tools for simultaneous inference with GLMM-based mixed parameter, we concentrate on their implementation and application to the well-known model-based estimators. These have been thoroughly examined in comparative analyses which included direct estimators (see for instance Boubeta, Lombardía, and Morales 2016; Hobza and Morales 2016). In our case study in Section 5, we include direct estimators in order to have an almost model-free benchmark.

5. Predicting Poverty Rates in Galicia

Poverty prediction is of great interest for statistical offices. It provides a basis on which local or central authorities can decide about resource allocation and related policies. The interest is not in individual, randomly chosen small areas but in the total picture. Resource distribution requires comparative statistics, and one would thus provide SCI instead of iCI. We illustrate our methodology calculating point estimates, iCIs and SCIs for the poverty rates in each county of Galicia, that is, the proportions of inhabitants who live under a poverty line. We make use of a general part of the Structural Survey for Homes (SSH) in Galicia in 2015 with 23,628 individuals within 9203 households located in 52 counties (small areas). The survey does not produce official estimates at the area level, but we managed to recover the direct estimates of the totals of people below the poverty line $(Y_d)$, as well as the number of inhabitants $(N_d)$ for each county. For the area-level models, we need to calculate the number of
units which fall into a particular category (X_{di}), for example, number of employees or of graduates in each county of Galicia, i = 1, . . . , p. The latter are used to obtain the proportions of individuals in each category \( \hat{\bar{X}}_{di} = X_{di}/N_d \). For the unit-level model, we need to obtain the number of units \( N_{dl} \) falling into artificially created categories \( z_{dl}, d = 1, \ldots, D, l = 1, \ldots, L \), see Section 2.2.3. The explicit formulas are

\[
\hat{\bar{X}}_{dir} = \sum_{j \in R_d} w_j y_{ij}, \quad \hat{N}_{dir} = \sum_{j \in R_d} w_j, \quad \hat{X}_{dir} = \sum_{j \in R_d} w_j y_{ij}, \quad \hat{\bar{X}}_{dir} = \hat{\bar{X}}_{dir}/\hat{N}_{dir}, \quad (25)
\]

where \( R_d \in \mathcal{P} \) are the sample elements belonging to area \( d \), \( d \in [D] \), \( w_j \) sampling weights, and \( y_{ij} \) binary variables with 1 indicating that an individual is below the poverty line. The poverty threshold is calculated from the survey. It is set to 0.6 of the median household income per capita in Galicia, that is, we do not use county specific poverty lines. This income is calculated in each household according to scale developed by the Organisation for Economic Co-operation and Development (the same technique is used by Eurostat). The model-based approach of this paper assumes that the estimates in Equation (25) are considered to be known, nonrandom quantities, following López-Vizcaíno, Lombardía, and Morales (2015). SSSI provides many categorical, auxiliary variables. Under the unit-level model these are binary variables with 1 indicating that a person belongs to a particular category, whereas under area-level models we use the county proportions. We considered four variables for labor status: children (ls0), employed (ls1), unemployed (ls2), inactive (ls3), and four covariates for education: less than primary (ed0), primary (ed1), first- and second-level secondary (ed2), higher education (ed3). Furthermore, we analyzed three variables for the size of municipality: less than 10,000 (sm1), 10,000–50,000 (sm2), more than 50,000 (sm3). We have also investigated the effect of two variables indicating the nationality, that is, Spanish (n1), not Spanish (n2). Finally, we examined five age variables: < 15 (age1), 15 – 24 (age2), 25 – 49 (age3), 50 – 64 (age4), >= 65 (age5). We are interested in \( \hat{\mu}_d^{(c)} := \mu_d^{(c)}/N_d \) with \( c \) standing for PG or U in case of Poisson-gamma and binomial model, respectively, and in \( \rho_d \) in case of the Poisson-lognormal model. We first compute estimates of proportions and their variances using the same formulas as Boubeta, Lombardía, and Morales (2016)

\[
\hat{\bar{P}}_d = \frac{\hat{\mu}_d}{\hat{N}_d}, \quad \hat{\bar{P}}_d = \frac{\hat{\bar{X}}_d}{\hat{N}_{dir}},
\]

\[
\text{var}(\hat{\bar{P}}_d) = \frac{1}{(\hat{N}_{dir})^2} \sum_{l \in R_d} w_l (1 - w_l) \left( \bar{y}_l - \hat{\bar{X}}_{dir} \right)^2, \quad (26)
\]

We used estimates in Equation (26) to construct design-based iCI intervals (Dir) displayed in Figure 3. Following López-Vizcaíno, Lombardía, and Morales (2015), we then proceed with a variable selection inspired by the simulation results. More specifically, under the Poisson-gamma model we check if any of the levels of categorical variables for labor status, education and age are significant at the \( \alpha = 0.05 \) level. We examined these covariates in the first place, because they turned out to be important in earlier studies on poverty rates (see, for instance, Boubeta, Lombardía, and Morales 2016). In this way, we selected ls2, ed2, and age2. Afterwards, we tested the levels of variables nationality and the size of the municipality and we additionally retained sm1 which was significant after the selection of ls2, ed2, and age2. The same categories were then used to other models, see Table 4. As we do not carry out a causality analysis, we refrain ourselves from a discussion of the magnitude or signs of estimates. We only notice that under the Poisson-gamma model, the signs are consistent with our expectations; unemployment and young age are associated with higher poverty rates, whereas higher level of studies or living in a small municipality is associated with lower poverty rates.

Figure 3 shows point and iCI estimates of proportions under Poisson-gamma (PG), Poisson-lognormal (PL), and binomial (Unit) models together with direct estimates (Dir). In this plot, we compare point estimates within four modeling frameworks; we do not compare them across different areas within the same model. First, the variability reflected by the width of iCIs decreases with the number of units in each area \( N_{dir} \) defined in Equation (25). Second, even though the area sample sizes \( n_d, d \in [D] \) are not that small, the iCI of direct estimates are wider than model-based estimates, which is in accordance with the literature. The width difference is especially pronounced when comparing area-level-based with design-based direct estimates—the latter entirely cover the former. Unit-level model-based point and interval estimates are different with much wider iCIs than under area-level models, but still overlapping with the direct estimates. Only in one case (sixth area in the third panel), the iCIs under area-level models do not overlap with the iCI under the unit-level model which indicates a possible bias in one of the approaches. In contrast, both area-level models produce almost identical estimates.

Figure 4 presents bootstrap iCI and SCI for \( \hat{\mu}_d^{PG} \), \( d = 1, \ldots, D \) constructed with \( \hat{\sigma}(\hat{\bar{P}}_d) = \sqrt{\var_{PG \bar{d}}} \) as defined in Equa-

![Figure 3](image-url)
Table 4. Estimates of regression parameters under the area- and the unit-level models with \( \hat{\delta}^{PG} = 2.48, \hat{\delta}^{PL} = 0.32 \) and \( \hat{\delta}^{U} = 0.35 \), respectively.

Finally, we investigate whether men and women are equally affected by poverty. We wish to test for equality on the county level across Galicia. Testing for each county individually at \( \alpha = 5\% \) error level results in rejection of at least 5% of the hypotheses of no significant difference. We thus use our MTP and consider clusters created from the cross section of sex and county such that \( \zeta \in \mathbb{R}^{104} \). We test \( H_0 : B\zeta = 0_{52} \) vs. \( H_1 : B\zeta \neq 0_{52} \) where \( B \in \mathbb{R}^{52 \times 104} \) with rows being vectors with 1 on the \( 2d - 1 \) place, \( -1 \) on \( 2d \) place, and 0 elsewhere. The max-type test statistic yields \( t_H = \max_{d=1,...,104} |B\zeta|/\hat{\delta}(\zeta) \approx 20.489 \) while the bootstrap critical value under \( H_0 \) is \( q_{BH0}^{1-(1-\alpha)} \approx 2.999 \). Thus, we strongly reject \( H_0 \). However, our test does not support the hypothesis that women are more affected than men, or vice versa, see the right panel of Figure 5. Additional results are deferred to our SM.

Remark 4. Imagine that Galician counties were considered as a part of a macro region, for example, Spain with \( D_S \) counties, and consider two inferential problems: (a) the calculation of SCI for the poverty rates in all \( D_S \) Spanish counties, (b) the calculation of SCI only for \( D \) Galician counties, but using all data. Following Remark 1, we expect that the widths of our SCI in Figure 4 would increase in case (a) to maintain the joint coverage probability of...
95% for all \(D_S > D\) counties. In contrast, they would most likely slightly decrease in case (b). In fact, the simultaneous coverage probability of 95% would be requested for the set of \(D\) counties, but SCI would be constructed using a more precise estimate of MSE computed using a larger dataset with \(D_S\) counties.

6. Conclusions

We developed a methodology that allows for statistically valid simultaneous inference for EBP under GLMM. We constructed SCI and MTP applying a combination of max-type statistics and consistent bootstrap estimation of its distribution. These tools enable practitioners to make comparisons between areas. In contrast, the iCIs are not suitable for such comparative analyses because they are constructed at individual confidence level and disregard an additional variation which arises in joint studies. We do not claim that SCI and MTP are better than iCIs or \(t\)-tests. The former simply complete the toolbox for statistical inference for mixed parameter \(l_\theta\). Similarly, the simultaneous inference completes the individual inference for fixed parameters. We introduced various versions of statistics to construct SCI and MTP. Within our framework, all of them exhibited similar performances without indicating a clear winner.

Our methodology can be extended to more complicated data structures such as GLMM with spatial or temporal correlation (see, e.g., Hobza, Morales, and Santamaria 2018; Chandra, Chambers, and Salvati 2019). One could also consider spatio-temporal or nonparametric models to build SCI by adjusting the statistic \(S_0\) and choosing a bootstrap procedure accordingly. Apart from a mathematical challenge to develop a valid asymptotic theory, these extensions would require a construction of an appropriate bootstrap scheme and its computationally efficient implementation.

Supplementary Materials

The supplementary materials consist of: (a) a document with further developments, in particular additional MSE decomposition, a proof of Proposition 1, the derivations of estimators under area-level Poisson and unit-level binomial models, additional numerical results and a data analysis which completes the case study in Section 5, (b) codes for replicating the results in the main document, and (c) a document which contains additional information on the data set and the description of the codes.

Appendix A: Technical details

A.1. Regularity conditions

In this section, we state the regularity conditions used in our derivations.

1. \(\hat{u}_d = \arg \max_{u_d \in \Theta} \log g_d(y_d | u_d, \theta) + \log h(u_d))\).
2. \(l(\theta)\) exists and is well-defined if: (a) \(l(\theta)\) is continuous, uniquely maximized and \(\theta_0 \in \Theta\), where \(\theta_0\) is a true parameter value; (b) \(l(\theta)\) and \(l(\theta)\) are concave; (c) \(\theta_0\) is an interior point of the parameter space and the estimator \(\hat{\theta}\) is an interior point of the neighborhood of \(\theta_0\); (d) \(\hat{l}(\theta)\) converges uniformly in probability to \(l(\theta)\).
3. \(x_d\) are bounded and \(E(y_d^n) < \infty\) for all \(d \in [D], j \in [n_d]\), where \(n_d\) is suitable large.
4. For each fixed \(y\), a score equation is continuously differentiable and \(E[R(\theta_{0j})] = 0\).

A.2. Proof of Proposition 2

Let \(y_{d_j} \sim \text{Exp}fam(\theta)\). If \(u_{d_j}^*\) is sampled from a suitable distribution, then we have \(y_{d_j}^* = M(E[y_{d_j} | u_{d_j}, \theta]) = x_d | \hat{\theta} + u_{d_j}^*\). Furthermore, \(\text{Var}^*(y_{d_j}^*) = \text{Var}(\text{Exp}(\text{Exp}(y_{d_j}^* | u_{d_j}^*))) + \text{Var}^*(\text{Exp}(y_{d_j}^* | u_{d_j}^*)))\). The first part of the Proposition follows from the way we generate the random effects as well as the results on the consistency of \(\hat{\theta}\). To show the second part we consider a general score equation. Replace \(y\) by \(y^*\) and set \(\theta = \hat{\theta}\), that is, \(R^*(\theta) = \frac{\partial R(\hat{\theta})}{\partial \theta} = \sum_{d=1}^D \frac{\partial \log f(y_d^*)}{\partial \theta} = 0\). Then \(E*(R^*(\theta)) = 0\) at \(\theta = \hat{\theta}\) which yields consistency of \(\hat{\theta}^*\).

A.3. Proof of Proposition 3

Let \(C_\theta\) be a general EBP, \(g_d := g_d(\theta)\) and \(\hat{g}_d := \hat{g}_d(\hat{\theta})\). Assume that \(||\hat{g}_d - g_d|| = O_p(n^{-c}), c > 0\). The proof uses ideas of Chatterjee, Lahiri, and Li (2008). We investigate the properties of \(G_d(a)\).

Applying some classical results and a triangle inequality, it follows that the last term is bounded by \(E[Q_f^2]\), and is of smaller order than the first three terms. Therefore, the first step toward the consistency of SCI is to quantify the asymptotic expansions of \(E[Q(a, y_d)]\) and \(E[Q_f^2(a, y_d)]\). We decompose \(Q(a, y_d)\) into \(Q(a, y_d) = Q_f^{-1/2}(\hat{\theta} - \hat{\theta}) + a_{g_d}^{-1/2}(\hat{\theta} - \hat{\theta}) = Q_1 + Q_2\). Let \(\psi\) be a twice differentiable function with respect to \(\theta, y_d = \{y_d, \ldots + y_{dD}, \forall D \in [D]\}\). Observe that \(y_d = \hat{y}_d\) under an area-level model. The specific form of \(\psi\) depends on the choice of the GLMM (for instance, under the Poisson-gamma model we spelled it out in Equation (7)). Function \(\psi\) satisfies the decomposition

\[
\hat{\theta} - \hat{\theta} = \psi_d(y_d, \hat{\theta}, \hat{\theta}) + o_p(||\hat{\theta} - \theta||^2).
\]

As for \(Q_1\), it has been found in Equation (A.1) that

\[
E(\hat{\theta} - \hat{\theta}) = \frac{1}{n} E \left[ \psi_d(y_d, \hat{\theta}) \right] \left[ \hat{\theta} - \theta \right] + o(n^{-c}).
\]
and $E(\hat{\xi}_d - \hat{\xi}_d)^2 = O(n^{-C})$, thanks to the result in Equation (A.2). Furthermore, observe that $g_d$ is of order $O(1)$ which leads to $E(Q_1) = O(D^{-c})$ as well as $E(Q_2) = O(D^{-C})$. When we turn to $Q_2$, we have an immediate simplification $Q_2 = \alpha_d^{-1/2}(\hat{\xi}_d^{1/2} - g_d^{1/2}) = a_1 \{ \hat{g}_d/g_d \}^{1/2} - 1$. Let $g_d$ be twice differentiable with respect to $\theta$. Similarly to the computations above, we have the expansion 

$$
\hat{g}_d(\hat{\theta}) = g_d(\theta) + \left( \frac{\partial}{\partial \theta} g_d(\theta) \right)^t (\hat{\theta} - \theta) + \frac{1}{2} (\hat{\theta} - \theta)^t \left( \frac{\partial^2}{\partial \theta^2} g_d(\theta) \right) (\hat{\theta} - \theta) + o_p(||\hat{\theta} - \theta||^2).
$$

Therefore, we obtain 

$$
E(\hat{g}_d(\hat{\theta})) = g_d(\theta) + \frac{1}{n^C} E \left[ \left( \frac{\partial}{\partial \theta} g_d(\theta) \right)^t nC (\hat{\theta} - \theta) \right] + O(n^{-C}).
$$

It follows that $E(\hat{g}_d/g_d)^{1/2} = O(n^{-C})$, $E(Q_2) = O(n^{-C})$ and $E(Q_2^2) = O(n^{-C})$. We can deduce that $G_d(a)$ attains the asymptotic expansion $G_d(a) = \Phi(a) + n^{-C} \gamma(n, a + O(n^{-C}))$. A similar expansion can be established for $G_d^*(a)$ if we replace $\theta$ with $\hat{\theta}$ and $P$ with $P^*$. 

### Funding

The authors gratefully acknowledge the support from the Swiss National Science Foundation for the project 200021-192345. In addition, they acknowledge the support from the MINECO grants MTM2017-82724-R and MTM2014-52876-R, the Xunta de Galicia (Grupos de Referencia Competitiva ED431C-2016-015 and Centro Singular de Investigación de Galicia ED431G/01), all of them through the ERDF. The computations were performed at the University of Geneva on the Baobab cluster.
