Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.
A novel combined dynamic ensemble selection model for imbalanced data to detect COVID-19 from complete blood count

COVID-19 screening
Imbalanced data
Dynamic ensemble selection
Hybrid multiple clustering and bagging
Candidate classifier generation

ABSTRACT

Background: As blood testing is radiation-free, low-cost and simple to operate, some researchers use machine learning to detect COVID-19 from blood test data. However, few studies take into consideration the imbalanced data distribution, which can impair the performance of a classifier.

Method: A novel combined dynamic ensemble selection (DES) method is proposed for imbalanced data to detect COVID-19 from complete blood count. This method combines data preprocessing and improved DES. Firstly, we use the hybrid synthetic minority over-sampling technique and edited nearest neighbor (SMOTE-ENN) to balance data and remove noise. Secondly, in order to improve the performance of DES, a novel hybrid multiple clustering and bagging classifier generation (HMBCCG) method is proposed to reinforce the diversity and local regional competence of candidate classifiers.

Results: The experimental results based on three popular DES methods show that the performance of HMBCCG is better than only use bagging. HMBCCG-KNE obtains the best performance for COVID-19 screening with 99.81% accuracy, 99.86% F1, 99.78% G-mean and 99.81% AUC.

Conclusion: Compared to other advanced methods, our combined DES model can improve accuracy, G-mean, F1 and AUC of COVID-19 screening.

1. Introduction

COVID-19, an epidemic caused by severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2), has ravaged over 200 countries around the world. As of October 4, 2020, more than 34.5 million cases and more than 1 million deaths have been reported worldwide [1]. Countries around the world have adopted strict quarantine and isolation measures to curb the spread of COVID-19. To prevent continued transmission, it is necessary to carry out effective screening for suspected cases in order to detect and isolate infected persons in time [2]. Currently, COVID-19 screening still relies heavily on reverse transcription polymerase chain reaction (RT-PCR) [3]. However, the missed detection rate of RT-PCR is about 15%-20% [4]. Moreover, it often takes hours or even days from collecting patient samples to obtaining test results [5]. Therefore, a more rapid and accurate COVID-19 detection method is needed.

Machine learning (ML) methods have been applied to detect COVID-19 due to their fast processing power and high reliability [6–9], such as deep convolutional network [10], ensemble learning [11] and enhanced k-nearest neighbor (KNN) [12]. Most of these methods are based on computerized tomography (CT) and X-ray image data. However, the relatively high cost and radiation doses hinder the large-scale application of CT. Although X-ray has lower cost and radiation compared to CT, its performance in COVID-19 screening is inferior to CT. In view of the low-cost, radiation-free and easy operation of blood testing, some researchers try to detect COVID-19 from blood test data through ML methods. Brinati, Campagner [4] studied the feasibility of several different ML models to predict COVID-19 infection from routine blood test data. However, the author did not deal with the imbalanced distribution of the dataset. Banerjee, Ray [5] used ML methods to predict COVID-19 infection from full blood count data. For community patients, the synthetic minority oversampling technique (SMOTE) is used to balance the positive (COVID-19 infection) and negative (absence of COVID-19 infection) classes. Then, the artificial neural network (ANN) is used to predict COVID-19 infection and achieved 87% accuracy. However, using SMOTE alone to deal with imbalanced data may generate outlier samples and reduce the classification accuracy [13]. Therefore, it is necessary to propose a better imbalanced data processing method to improve the accuracy of COVID-19 screening from blood test data.
From the current research, the methods of dealing with imbalanced data can be roughly divided into two types: data-based methods and algorithm-based methods [14]. Data-based methods mainly include over-sampling [13], under-sampling [15] and hybrid sampling [16]. For algorithm-based methods, it can be divided into cost-sensitive learning [14] and ensemble learning [17]. The purpose of cost-sensitive learning is to minimize the cost of misclassification on the premise that the cost of misclassification is known [18]. However, for real-life problems, the prior knowledge of the cost of misclassification is often unknown, which makes the application of cost-sensitive learning difficult. Ensemble learning can improve the generalization ability to existing algorithms and has been proven to be an effective method for imbalanced data processing. Among the many ensemble learning approaches, dynamic ensemble selection (DES) as a very promising method has been proved by a large number of studies to be superior to static ensemble learning [19–21]. For a DES technique, the neighbors of each test sample, called the competence region, are used to measure the competence of each candidate classifier. Then DES selects appropriate classifiers for each test sample based on the competence measurement to form an ensemble, rather than using a unified ensemble for all test samples.

Recently, more and more DES methods have been applied to deal with imbalanced data problem and have achieved outstanding performance [20, 22, 23]. Roy, Cruz [24] compared the performance of DES combined with a preprocessing technique and static ensemble for processing imbalanced data. The experimental results show that DES have higher F-measure and G-mean relative to static ensemble methods. Hou, Wang [20] combined SMOTE and DES to assess credit risk, and tested the performance of the hybrid method on other 15 imbalanced datasets. However, these DES methods mainly use bagging [25] to train candidate classifiers, and the training sets randomly generated by bagging may not be sufficient to represent the competence regions. Moreover, these studies set fixed parameters for the base classifiers, which may reduce the fitting performance of base classifiers to different training sets.

To solve the above-mentioned problems and challenges, a novel combined DES method is proposed for imbalanced data to detect COVID-19 from complete blood count. At the data level, hybrid SMOTE and edited nearest neighbor (SMOTE-ENN) [26] is used to balance data and clean up noise. At the algorithm level, in order to improve the competence in local regions and diversity of candidate classifiers, a novel hybrid multiple clustering and bagging classifier generation (HMCBCG) method is developed to improve DES. HMCBCG adds multiple clustering to generate classifiers on the basis of bagging. Specifically, we use k-means [27] with different k values to cluster the training set repeatedly with replacement. In this way, multiple clusters with different decision boundaries can be generated, which increases the diversity of candidate classifiers. Besides, the training sets generated based on clustering are more likely to represent the local regions around the test samples than bagging. Then, all the clusters obtained by multiple clustering are used to train support vector machines (SVM) [28]. At the same time, for each cluster, we use genetic algorithm (GA) [29] to optimize the parameters of SVM to strengthen its regional competence and diversity. Finally, the base classifiers generated by bagging and SVMs based on clustering training are mixed together to form a candidate classifier pool. The contributions of this research can be summarized as:

I. A combined DES method is proposed for imbalanced data to detect COVID-19 from complete blood count.
II. A novel HMCBCG candidate classifier generation method is developed to improve the performance of DES.

III. The proposed combined DES method can significantly improve the accuracy, G-mean, F1 and area under the curve (AUC) of COVID-19 screening than other compared advanced algorithms.

IV. HMBCG+k-nearests oracles eliminate (KNE) obtains the best performance for COVID-19 screening with 99.81% accuracy, 99.86% F1, 99.78% G-mean and 99.81% AUC.

The rest of this paper is organized as follows: Section 2 introduces previous related work. Section 3 describes the dataset and methods used in this study. In Section 4, we present the experimental setting, performance metrics, and experimental results. Section 5 provides a discussion about the experimental results. Finally, a brief summary is described in last section.

2. Related work

2.1. Intelligent computing methods in COVID-19 screening

Currently, intelligent computing methods of COVID-19 screening are mainly based on CT, X-ray and clinical blood test data. In terms of CT and X-ray, the convolutional neural network (CNN) is the most used method. Ezzat, Hassanien [30] proposed a gravity search optimized CNN to detect COVID-19 from a dataset containing CT and X-ray images, which accuracy is 98.38%. Apostolopoulos and Mpesiana [8] combined transfer learning technology with several advanced CNNs to diagnose COVID-19. The MobileNet performed best in experimental results with 96.78% accuracy. In addition, there are also some studies using other ML techniques to detect COVID-19 from medical imaging data. Chandra, Verma [11] proposed an ensemble learning method based on majority voting to detect COVID-19 from X-ray and its accuracy is 98.062%. Shaban, Rabie [12] produced a new COVID-19 detection strategy that combining feature selection and improved KNN. The recognition accuracy of this method for COVID-19 CT images is 96%. Compared with CT and X-ray, blood testing has the advantages of low-cost, radiation-free and easy operation. Therefore, some studies try to using ML to detect COVID-19 from blood test data. For example, Brinati, Campagner [4] studied several ML methods to detect COVID-19 from blood routine examination data. The results show that random forest achieved the highest accuracy. However, this study did not notice the negative impact of imbalanced data distribution on classification performance. Especially for a dataset where the number of healthy people is much larger than the number of COVID-19 infections, classifier will tend to identify healthy people and ignore infected people. Unfortunately, the cost of misdiagnosing an infected person as a healthy person is far greater than the cost of misdiagnosing a healthy person as an infected person. Although Banerjee, Ray [5] applied SMOTE to balance the different classes in the dataset for detecting COVID-19 from full blood count data, there is still room for improvement.

2.2. DES to handle imbalanced data

DES, one of the dynamic selection (DS) techniques, has been shown to outperform single-based classifiers for some classification problems [31]. DES techniques are recommended for handling imbalanced data problems since they perform local classification [32]. In recent years, more and more studies have proved that DES are superior to static ML algorithms for imbalanced data processing. We roughly classify the existing DES methods for dealing with imbalanced data into two categories. One is to directly improve DES without combining resampling methods. For example, Oliveira, Cavalcanti [33] proposed FIRE-DES algorithm to preselect those classifiers that have the ability to process decision boundary samples when the test sample is in an overlapping area. Experiments prove that FIRE-DES can improve the performance of existing DES frameworks for small imbalanced data processing. Junior,
Nardini [22] developed an improved KNN to balance the sample distribution in the local region of the test sample. The intuition of this algorithm is to reduce the distance between the minority samples and the predicted sample so that more minority samples are included in the neighbors of the predicted sample. Zhao, Wang [34] introduced patch learning in DES to improve the diversity of base classifiers. Experimental results show that this patched-ensemble model performs well for multi-class imbalanced classification. Zyblewski, Woźniak [35] designed two DES methods, which are based on Euclidean distance and imbalance rate to select base classifiers. The effectiveness of these two DES methods was tested on 41 high imbalance ratio datasets.

Another kind of method is to combine preprocessing with DES to deal with imbalanced data. Zyblewski, Sabourin [36] proposed a framework that integrates data preprocessing and DES for imbalanced data stream classification. This approach uses stratified bagging to train the base classifiers. Cruz, Oliveira [37] proposed FIRE-DES ++ algorithm, which improves FIRE-DES by removing noise and using the same number of instances of each class to define the competence region. Gao, Ren [23] presented a method of combining hybrid sampling based on data partition with dynamic model selection for imbalanced data. In addition, García, Zhang [38] proposed a method that hybrid preprocessing and DES to handle multi-class imbalanced data. The preprocessing part of the method obtains a balanced training set through resampling. In the candidate classifier selection part, the classifiers with a strong ability to recognize minority samples are preferentially selected through the mechanism of weighting the competence region.

However, from our knowledge, most of these DES methods are based on bagging to generate candidate classifiers. The training sets generated by random sampling of bagging may not be sufficiently representative of the competence regions. In addition, using fixed parameters to generate candidate classifiers is a common practice in existing DES methods, which may lead to insufficient fitting to the training set.

3. Materials and Methods

3.1. Data collection

The dataset for this study is obtained from the data science platform Kaggle. This dataset has been used for COVID-19 diagnosis through intelligent computing methods in previous research [5][55-57]. The original dataset contains 5644 cases with 111 attributes. It was provided by Hospital Israelita Albert Einstein in Sao Paulo, Brazil. Patients in the dataset were tested for COVID-19 by RT-PCR during their visit to the hospital, and other laboratory tests were also performed. All patients have been anonymized. There are a lot of missing values in the original dataset. We preprocessed the dataset as follows: First, we remove the features that are mostly missing values, and 17 features including SARS-CoV-2 test and standard complete blood count are remained. Then, samples with mostly null are also removed, and 603 cases are obtained. The distribution of negative samples and positive samples is imbalanced, being 520 and 83, respectively. Finally, multivariate imputation by chained equation (MICE) [39] is used to fill in missing values in the selected samples.

Table 1 shows the filtered features and data types. As shown in Table 1, the “SARS-CoV-2 exam result” is a binary label, negative means no COVID-19 infection, and positive means COVID-19 infection. All features except “SARS-CoV-2 exam result” are numerical features. Fig. 1 shows the sample distribution of the selected features. Fig. 2 reports the Pearson correlation coefficient of the selected features. The darker the color, the stronger the positive correlation between the two features. The lighter the color, the stronger the negative correlation.

3.2. SMOTE-ENN for preprocessing

In this paper, SMOTE-ENN is used to preprocess the COVID-19 dataset. SMOTE-ENN is a hybrid sampling method proposed by Batista, Prati [26]. SMOTE-ENN combines the advantages of both SMOTE [40] and edited nearest neighbor [41] [42], which can effectively deal with imbalanced data and remove noise. In SMOTE, a new sample is synthesized according to Eq. (1):

\[ x_i = x + \text{random}(0, 1) (x - x) \]

where, \( x \) is a new synthesized sample; \( x \) represents a minority sample (positive sample); \( x \) is a randomly selected sample from the k nearest neighbors of \( x \); \text{random}(0,1) represents a random number between 0 and 1. As a simple and effective oversampling method, SMOTE is widely used to deal with imbalanced data. ENN can identify and remove noise to make the decision boundary smoother [37]. ENN uses KNN to predict each sample in the new dataset. If the predicted result is inconsistent with the real label, the sample is removed.

3.3. HMBCG model to improve DES

In order to strengthen the diversity of DES candidate classifiers and their regional competence, we propose a novel HMBCG algorithm to generate candidate classifiers. As shown in Algorithm 1 and Fig. 3, candidate classifiers generated by HMBCG consists of two parts: one part is generated by multiple times k-means clustering with different k values, and the other part is established by bagging. In this way, subsets generated by clustering tend to have better local regional representation than the randomly generated subsets by bagging. Moreover, subsets generated by multiple times clustering based on different cluster numbers can increase the diversity of the training set. Therefore, candidate classifiers generated by combining multiple times clustering based on different cluster numbers with bagging have better diversity and local capabilities than bagging alone.

Firstly, in part of generating candidate classifiers based on clustering, we cluster the training set multiple times by k-means with different k values. After each k-means clustering, we put the samples back in order to cluster the original training set again. The number of clusters for each time is taken from 2 to the preset maximum number of clusters k_max. For example, assuming that

Algorithm 1
HMCBCG model

Input: Train data Dn, maximum cluster numbers kmax, m base learners L1, L2, ..., Ln. Set the number of samples in each subset obtained by bagging to n.
Output: Candidate classifier pool \( \Psi \)

1: \( \Psi = \emptyset \)
2: for 2 to \( k_{\text{max}} \) do:
3: Use k-means to divide \( D_n \) into \( k \) clusters.
4: for each cluster do:
5: Apply GA to optimize SVM to get the SVM with optimal parameters.
6: Add the trained SVM to \( \Psi \).
7: end for
8: Shuffle all the clusters to restore \( D_n \).
9: end for
10: for 1 to \( m \) do:
11: for 1 to \( n \) do:
12: Randomly draw a sample from \( D_n \).
13: end for
14: Use the \( n \) samples to train a base learner.
15: Add the trained base learner to \( \Psi \).
16: Put the \( n \) samples back to restore \( D_n \).
17: end for
18: return \( \Psi \)

Fig. 3. Specific steps of our proposed combined DES method for COVID-19 screening. \( k \) represents the number of clusters set for each time. \( k_{\text{max}} \) is the maximum number of clusters. \( \Psi_i \) is the \( n \) samples randomly selected from the training set for the \( i \)-th time. \( L_i \) is the base classifier obtained by training with \( \Psi_i \) and \( m \) is the number of base classifiers.

where \( \lambda_i \) represents the weight vector, \( \Phi \) means input vector and \( b \) is the bias. Eq. (2) can be transformed into an optimization problem as

\[
\min_\psi \frac{1}{2} \psi^T \psi \quad \text{s.t.} \quad y_i (\psi^T x_i + b) \geq 1 \quad i = 1, 2, ..., n
\]

By introducing Lagrangian multipliers with \( \lambda_i > 0 \text{ for } i = 1, 2, ..., n \), the optimization problem can be transformed into a dual problem as follows:

\[
\min_\psi \frac{1}{2} \sum_{i=1}^{n} \sum_{j=1}^{n} y_i y_j \lambda_i \lambda_j (x_i \cdot x_j) - \sum_{i=1}^{n} \lambda_j
\]

\[
\text{s.t.} \quad \sum_{i=1}^{n} \lambda_i y_i = 0, \quad 0 \leq \lambda_i \leq C, \quad i = 1, 2, ..., n
\]

where \( C \) is the penalty coefficient. If \( C \) is too large, the risk of SVM falling into over-fitting will increase; otherwise, under-fitting will easily occur. For nonlinear problems, SVM needs to map the original data to a high-dimensional space through a kernel function to make it linearly separable. The classification function can be expressed as

\[
\hat{f}(x) = \text{sgn} \left( \sum_{i=1}^{n} \lambda_i y_i K < x_i \cdot x_j > + b \right)
\]
where $\lambda_\nu^*$ indicates the optimal Langrangian coefficient, $b'$ denotes the optimal bias. $\text{Sgn}(\cdot)$ is a symbolic function. $K < \mathbf{x}_i \cdot \mathbf{x}_j >$ represents the kernel function. In this study, we chose the most commonly used radial basis function (RBF) as the kernel function of SVM. The RBF kernel function is expressed as:

$$K < \mathbf{x}_i \cdot \mathbf{x}_j > = e^{-\eta \| \mathbf{x}_i - \mathbf{x}_j \|^2} \quad (6)$$

The performance of SVM is greatly affected by the penalty coefficient $C$ and the kernel function parameter $\eta$. In previous studies, SVM as the base classifier of DES often uses fixed parameters. In order to improve the regional competence and diversity of SVM, this paper uses GA to optimize the penalty coefficient $C$ and the kernel function parameter $\eta$ of SVM. GA is a method that searching for the optimal solution by imitating the selection, crossover and mutation in the natural evolution process. Due to the outstanding global optimization ability of GA, it has been well applied to optimization problems in many fields. In view of the above advantages, GA is used to optimize the penalty factor and the kernel function parameter of SVM. The classification accuracy of SVM is used as the fitness of GA. In this way, for each cluster, SVM with the optimal parameters is obtained.

Another part of candidate classifiers is generated by bagging. Bagging is a typical ensemble learning method, which improves prediction accuracy and robustness by combining multiple base classifiers, and can reduce variance and avoid overfitting. The specific steps of bagging are: (1) Randomly select $n$ samples from the original dataset. (2) Use the obtained $n$ training samples to train a base classifier. (3) Repeat steps (1) and (2) $m$ times. The prediction result is decided by the $m$ base classifiers collectively (usually by voting).

Finally, the candidate classifiers generated by bagging and SVMS based on clustering training are mixed to construct a DES candidate classifier pool.

3.4. Specific steps of proposed combined DES model for COVID-19 screening

Based on SMOTE-ENN preprocessing and HMCBCG optimized DES, we propose a combined DES model for imbalanced data to detect COVID-19 from complete blood count. Fig. 3 shows the flow chart of our proposed combined DES model. The specific implementation steps are as follows:

(1) Perform data cleaning on the original dataset $D$, including feature selection and filling in missing values. Then apply SMOTE-ENN to balance the different classes in the dataset and remove noise samples. Finally, receive the cleaned dataset $D_c$.
(2) Divide $D_c$ into training set $D_{train}$ and testing set $D_{test}$. A part of samples is randomly selected from $D_{train}$ as the validation set, which is also called dynamic selection dataset (DSEL) [37]. The remaining samples are denoted as $D_{tr}$.
(3) The candidate classifier pool $\Psi$ is generated based on the $D_{t}$ and HMCBCG method.
(4) For a query sample $\mathbf{x}_i$ in the testing set, select its $k$ neighbors from DSEL.
(5) Each classifier in $\Psi$ is used to classify the $k$ nearest neighbors selected from DSEL.
(6) Select suitable classifiers from $\Psi$ according to the selection criteria (usually by accuracy).
(7) Combine the selected classifiers according to majority voting.
(8) Determine and output the class of the query sample $\mathbf{x}_i$.

Table 2

| Confusion matrix | Actual Positive | Actual Negative |
|------------------|-----------------|-----------------|
| Predicted Positive | TP | FP |
| Predicted Negative | FN | TN |

4. Experiments and results

4.1. Experiment setting

In this research, we chose three DES methods, including KNE [43], KNU [43] and DESKNN [44] to test the proposed HMCBCG model. We considered several configurations $k_{\text{max}} = 2, 3, 4, 5$ and the classifier generation that only uses bagging, which is recorded as NON in the experimental results. The experiment considered three data division methods of 70-30, 60-40 training-test divisions and 5-fold cross-validation. Naive bayesian [45], decision tree (DT) [46], KNN [47] and RF [48] are selected as base classifiers to train with bagging. We set the number of each type of base classifier to 10, that is, a total of 40 base classifiers are trained by bagging. In addition, the GA operators use tournament selection, uniform crossover and flipbit mutation. Set the crossover probability to 0.8 and the mutation probability to 0.1. The population size is 50 and the number of iterations is 30.

We also compared our combined DES method with several advanced algorithms, including GBDT [49], SVM, RF, LR [50] and XGBoost [51]. In this study, all the computations are performed on a Python 3.6 platform on a Windows 10 system with Intel Core i5 (1.6 GHz, 8 CPUs) with 8 GB of RAM. The results of this study are the average performance after repeating the experiment 10 times.

4.2. Performance metrics

In this research, we choose accuracy, G-mean and F1 as the evaluation indicators, which are widely used in the performance evaluation of algorithms on imbalanced data. They can be defined according to the confusion matrix in Table 2. Accuracy, G-mean and F1 are shown as follows:

Accuracy = \[\frac{TP + TN}{TP + TN + FP + FN}\] \quad (7)

$$G - \text{mean} = \sqrt{\frac{\text{sensitivity} \times \text{specificity} = \frac{TP}{TP + FP} \times \frac{TN}{TN + FP}}}}$$ \quad (8)

$$F1 = \frac{2 \times \text{precision} \times \text{recall}}{\text{precision} + \text{recall}}\quad (9)$$

where precision = \[\frac{TP}{TP + FP}\], recall = \[\text{sensitivity} = \frac{TP}{TP + FN}\].

AUC is the area under the receiver operating characteristic curve (ROC). The closer the AUC is to 1, the better the performance of the classifier. AUC is very suitable for evaluating imbalanced data classifiers because it is insensitive to the proportion of positive and negative examples in the dataset [52].

4.3. The performance of HMCBCG for different DES algorithms

The experimental results of KNE, KNU and DES-KNN under 70-30, 60-40 divisions and 5-fold cross-validation are shown in Table 3-5, respectively. For the four indicators of accuracy, F1, G-mean and AUC, we have marked the best results of KNE, KNU and DES-KNN in bold. As shown in Fig. 4-6, in order to better compare
Table 3
Mean performance and standard deviations of KNE, KNU and DESKNN under different $k_{max}$ values with 70-30 division.

| Metrics | Methods | NON | $k_{max}=2$ | $k_{max}=3$ | $k_{max}=4$ | $k_{max}=5$ |

Fig. 4. Average performance and standard deviations comparison of KNE, KNU and DESKNN under different indicators with 70-30 division. (a) Accuracy, (b) AUC, (c) F1, (d) G-mean.

The performance of KNE, KNU and DESKNN for different $k_{max}$ values, we have drawn bar charts of different indicators for the three division methods of 70-30, 60-40 training-test and 5-fold cross-validation.

It can be seen from Fig. 4-6 that for different training-test divisions and $k_{max}$ values, the performance of HMCBG is improved on accuracy, F1, G-mean and AUC for KNE, KNU and DES-KNN compared with bagging directly. This shows that for different $k_{max}$ values, HMCBG can not only effectively improve the overall accuracy of COVID-19 detection, but also improve the sensitivity and specificity. From Fig. 4-6, we can see that HMCBG+KNE obtains the best performance with 99.81% accuracy, 99.86% F1, 99.78% G-mean and 99.81% AUC when $k_{max} = 5$ with 70-30 division.

As can be seen from Table 3-5 and Fig. 4-6, on the whole, with the increase of $k_{max}$, the values of accuracy, F1, G-mean and AUC of KNE, KNU and DESKNN also increase. This is because as the value of $k_{max}$ increases, the more different clusters are generated, the more diverse SVMs after training. In addition, GA enhances the adaptability of SVMs to different clusters. In this way, the larger the value of $k_{max}$, the more likely the optimized SVMs are to fit different competence regions of different query samples, and the higher the accuracy of DES.
For Table 3, when $k_{\text{max}}=5$, we observe that the values of 99.04% accuracy, 99.20% F1, 99.21% G-mean and 99.04% AUC of KNU have a slight decrease relative to $k_{\text{max}}=4$ which are 99.52% accuracy, 99.61% F1, 99.57% G-mean and 99.52% AUC. Similar situations can also be observed when the $k_{\text{max}}=3, 4$ of KNE and $k_{\text{max}}=2, 3$ of DES-KNN from Table 4 and Table 5. This shows that for different data partitioning methods, the performance of KNE, KNU and DES-KNN may fluctuate slightly with the increase of $k_{\text{max}}$, but overall it will improve with the increase of $k_{\text{max}}$. Another interesting observation is that whether it is 70-30, 60-40 divisions or 5-fold cross-validation, for different $k_{\text{max}}$ values, HMCBCG+KNE outperforms HMCBCG+KNU and HMCBCG+DES-KNN in terms of accuracy, F1, G-mean and AUC.

In terms of standard deviation, we can see from Table 3 and Fig. 4 that for different values of $k_{\text{max}}$, the standard deviations of KNE, KNU and DES-KNN for all four evaluation metrics are less than bagging under the data division of 70-30. As seen in Tables 4 and Table 5, the standard deviations of KNE, KNU and DES-KNN for accuracy, F1, G-mean and AUC are comparable to bagging for both $k_{\text{max}}=2$ and $k_{\text{max}}=3$ for the 60-40 and 5-fold cross-validation data partitioning methods, while the standard deviations of these three DES methods are better than bagging when $k_{\text{max}}=4$ and $k_{\text{max}}=5$. Therefore, in most cases, the standard deviations of the improved DES based on HMCBCG are lower than that of the DES with only bagging to generate candidate classifiers, which indicates that our method has better stability and consistency.

Fig. 5. Average performance and standard deviations comparison of KNE, KNU and DES-KNN under different indicators with 60-40 division. (a) Accuracy, (b) AUC, (c) F1, (d) G-mean.

|           | DES-KNN   | 0.9654±0.0123 | 0.9668±0.0077 | 0.9889±0.0079 | 0.9914±0.0051 | 0.9961±0.0037 |
To further verify the superiority of HMCBCG over bagging, the experimental results of KNE, KNU and DES-KNN under different \( k_{\text{max}} \) values are subjected to paired t-tests with bagging, respectively. The paired t-test is recommended for the comparison of two classifiers on one dataset \([53, 54]\). A p-value less than 0.05 is considered statistically significant in this study. Tables 6–8 show the results of paired t-tests under 70-30, 60-40 divisions and 5-fold cross-validation, respectively. As can be seen in Tables 6–8, except for DES-KNN at \( k_{\text{max}} = 2 \) under 60-40 partitioning, for different data divisions and DES methods, the accuracy, F1, G-mean and AUC of HMCBCG under different \( k_{\text{max}} \) values are significantly better than bagging.

### 4.4. Comparison of other advanced classifiers

Table 9 shows the performance and standard deviations comparison of HMCBCG+KNE, HMCBCG+KNU and HMCBCG+DES-KNN with other advanced classifiers in term of 5-fold cross-validation when \( k_{\text{max}} = 5 \). It can be seen from Table 9 that accuracy, F1, G-mean and AUC of HMCBCG+KNE, HMCBCG+KNU and HMCBCG+DES-KNN are higher than other advanced algorithms. HMCBCG+KNE obtains the best performance with 99.76% accuracy, 99.80% F1, 99.69% G-mean, 99.69% AUC. Furthermore, as can be seen in Table 9, HMCBCG+KNE, HMCBCG+KNU and HMCBCG+DES-KNN all produced smaller standard deviations than
the other compared classifiers in terms of accuracy, F1, G-mean and AUC. This indicates that our proposed DES methods have better stability than the other five competitors.

In addition, as shown in Table 11, paired t-tests are performed to compare the proposed combined DES approach with other classification algorithms. As can be seen in Table 11, with 5-fold cross-validation, HMCBCG+KNE, HMCBCG+KNU and HMCBCG+DESKNN outperformed the other five advanced classifiers in terms of accuracy, F1, G-mean and AUC at the 5% significance level ($k_{max}=5$).

Fig. 7 further compares the ROC curves of HMCBCG+KNE, HMCBCG+KNU and HMCBCG+DESKNN with other advanced algorithms. It can be seen from Fig. 7 that AUC values of HMCBCG+KNE, HMCBCG+KNU and HMCBCG+DESKNN are signifi-

significantly greater than other comparative algorithms. This shows that our combined DES method can simultaneously improve the detection accuracy of COVID-19 negative and positive. For a COVID-19 dataset, if the number of healthy cases is much larger than the number of virus carriers, this will cause the classifier to pay too much attention to the majority samples and a decline in the classification accuracy of the minority samples. Obviously, the cost of misclassifying a COVID-19 carrier as healthy is much greater than misdiagnosing a healthy person as COVID-19 infected. Therefore, our proposed combined DES method is more suitable for COVID-19 screening from imbalanced complete blood count data than other advanced algorithms.

5. Discussion

In this study, a hybrid DES imbalanced data processing method is proposed to detect COVID-19 from complete cell count data. We use SMOTE-ENN to balance data distribution and clean up noise. Moreover, the HMCBCG model is proposed to improve the diversity and local capabilities of DES candidate classifiers.

We use three popular DES algorithms including KNE, KNU and DESKNN to test the performance of the proposed HMCBCG method. Then we compared the performance of the proposed combined DES model with other advanced classifiers for COVID-19 screening. As shown in Table 10, we also compared the proposed method with previous studies. It can be seen from Table 10 that HMCBCG+KNE has better accuracy than other methods in the literature.

The key findings of the experimental results are summarized as follows: (1) For the three DES algorithms KNE, KNU and DESKNN, the performance of our HMCBCG is better than generating classifiers only by bagging. (2) HMCBCG+KNE obtains the best performance for COVID-19 screening with 99.81% accuracy, 99.86% F1, 99.78% G-mean and 99.81% AUC when k_{max} = 5 with 70-30 division. (3) Our proposed combined DES model is significantly better than several other advanced algorithms for COVID-19 screening, including GBDT, SVM, RF, LR and XGBoost in terms of accuracy, F1, G-mean and AUC.

These findings indicate that whether for traditional DES methods or others advanced single classifiers and static ensemble algorithms, our combined DES model has certain advantages for predicting COVID-19 infection from imbalanced complete blood count data. This method can be explored as a decision support tool for clinical practice to isolate and provide medical services for patients with COVID-19 as soon as possible, thereby optimizing the allocation of medical resources. The main limitation of this article is the sample size of the dataset. The performance of the proposed method can be enhanced by larger datasets containing patients from different regions and different hospitals.

The ROC curves of HMCBCG+KNE, HMCBCG+KNU and HMCBCG+DESKNN with other advanced algorithms

6. Conclusion
In this paper, we propose a novel combined DES method for imbalanced data to detect COVID-19 from complete blood count data. This model combines data preprocessing and improved DES. Firstly, SMOTE-ENN is used for data preprocessing to balance the number of samples of different classes and clean up noise. Secondly, the HMCBCG method is proposed to generate candidate classifiers to improve the performance of DES. Experimental results show that our combined DES algorithm is superior to other comparative state-of-the-art methods in detecting COVID-19 from complete blood count data. In the future, we plan to use the proposed approach to detect COVID-19 from a larger complete blood count dataset. Moreover, we consider applying our model to other diseases based on imbalanced data to further test the effectiveness of the proposed method.

7. Conflicts of Interest
The authors declare no conflicts of interest.
