(Dated: February 12, 2015)

The apparent anisotropies of the galaxy clustering in observable redshift space provide a unique opportunity to simultaneously probe cosmic expansion and gravity on cosmological scales via the Alcock-Paczynski effect and redshift-space distortions. While the improved theoretical models have been proposed and developed to describe the apparent anisotropic clustering at weakly non-linear scales, the applicability of these models is still limited in the presence of the non-perturbative smearing effect caused by the randomness of the relative velocities. Although the cosmological constraint from the anisotropic clustering will be certainly improved with a more elaborate theoretical model, we here consider an alternative way by using the statistical power of both the power spectrum and bispectrum at large scales. Based on the Fisher matrix analysis, we estimate the benefit of combining the power spectra and bispectra, finding that the constraints on the cosmic expansion and growth of structure will be improved by a factor of two. This compensates for the loss of constraining power using the power spectrum alone due to the randomness of the relative velocities.

PACS numbers:

I. INTRODUCTION

In our current understanding of the universe, an unknown substance called dark matter dominates over the standard model particles at the present epoch. Despite many theoretical and observational efforts, the origin of dark matter is not yet clarified. Also, the existence of dark energy, which is supposed to drive the cosmic acceleration, indicates our incomplete understanding of the gravity on cosmological scales. It may imply modifications to Einstein’s theory of General Relativity. A further insight into the origin and nature of dark energy or validity of general relativity is essential, and this is one of the primary goals in next-generation cosmology.

The large-scale structure offers an opportunity to probe these issues by looking at the anisotropic galaxy clustering in redshift space. The observed galaxy distribution via the spectroscopic measurements is apparently distorted due to the peculiar velocity of galaxies along the line-of-sight direction, referred to as the redshift-space distortions (RSD). While the RSD complicate the interpretation of the small-scale galaxy clustering, on large scales, the strength of anisotropies is simply characterized by the linear growth rate $f = d\ln \delta_m / d\ln a$ [3], providing us a unique opportunity to probe the growth of structure, where $\delta_m$ and $a$ are the linear density field and scale factor of the Universe, respectively. On the other hand, the large-scale galaxy clustering data imprints the fossil record of primeval baryon-photon fluid around the last-scattering surface, known as the baryon acoustic oscillations (BAO). The characteristic scales of BAO can be used as standard ruler, which enables us to determine the geometric distances at high-$z$ galaxies with a greater precision. The key point to determine the geometric distances is to measure the clustering anisotropies over the BAO scales. Notice the fact that the anisotropies of the clustering pattern also arises from the apparent mismatch of the underlying cosmological model when we convert the redshift and angular position of each galaxy to the co-moving radial and transverse distances. This is the so-called Alcock-Paczynski (A-P) effect, and with a prior knowledge of the characteristic scale of the BAO, the Hubble parameter $H(z)$ and angular diameter distance $D_A(z)$ at the high-$z$ galaxies can be separately measured. To sum up, the anisotropic galaxy clustering can serve as a dual cosmological probe, from which we can explore the origin of cosmic acceleration from the viewpoint of both dark energy and modification of gravity.

In order to simultaneously extract the information on both the growth of structure and cosmic expansion, a detailed theoretical modeling of the anisotropic clustering is critical. While the scales of our interest are rather close to the linear regime of structure formation, there appear small but non-negligible nonlinear systematics to be corrected or subtracted, including the nonlinear grav-
In this paper, we present the combined results of the power spectra and bispectra to constrain the geometric distances and growth of structure. The present paper is partly similar to [33], but is rather different in several aspects. To be specific, we consider a future accessible spectroscopic survey like Dark Energy Spectroscopy Instrument (hereafter DESI), which would be the best suited to probe the cosmic acceleration around $z \sim 1$. With this survey setup, we discuss the impact of the Finger-of-God effect on the estimation of cosmological parameters, which has not been considered in [33]. We show that while the uncertainty of the Finger-of-God effect in power spectra is mostly degenerate with the coherent motion as a probe of the growth of structure, the combination of power spectra and bispectra breaks this degeneracy, thus improving the measurement accuracy of the coherent motion by a factor of two. As for the constraints on geometric distances, substantial improvement is found, consistently with previous works. Furthermore, role of the non-vanishing cross covariance between power spectra and bispectra is studied, and the relative impact in estimating the statistical errors is quantified, finding that the influence of cross covariance is small enough in weakly nonlinear regime.

This paper is organized as follows. In Sec. III, the basic setup of the forecast analysis is presented. Based on the perturbation theory, theoretical models for power spectra and bispectra are given, taking account of both the A-P effect and RSD. Then, the basic formalism for Fisher matrix analysis is described, including the cross covariance between power spectra and bispectra. Sec. III presents the main results for Fisher matrix analysis. After comparing the signal-to-noise ratios of power spectra with those of bispectra, we show the expected constraints on geometric distances ($D_A$ and $H$) and growth of structure $f$ in DESI-like experiments. The impact of Finger-of-God effect is discussed in detail, and role of the bispectra is clarified. Finally, Sec. IV is devoted to the summary and discussion.

II. CONSTRAINTS ON COSMOLOGY USING POWER SPECTRUM AND BISPECTRUM

A. Power spectrum

On large scales of our interest, the density and velocity fields are basically the small perturbations to the homogenous background. When the higher-order contributions are ignorable, the power spectra is simply described by the linear theory, and in redshift space, it is given by

$$\tilde{P}_\text{lin}(\vec{k}) = Z_1^2(\vec{k}) P(\vec{k}),$$

where $Z_1(\vec{k})$ is defined by,

$$Z_1(\vec{k}) = b + f \mu^2 .$$

The linear galaxy bias, denoted by $b$, represents the enhancement of the clustering amplitude relative to the...
mass density field $\delta_m$. The function $f$ is defined by the logarithmic derivative of the linear density field with respect to the logarithm of scale factor, i.e., $f = d \ln \delta_m/d \ln a$. The directional vector $\vec{k}$ is decomposed into $(\hat{k}, \mu)$ where $\mu$ denotes the cosine of angle to the line of sight.

In practice, the applicability of the linear theory expression in Eq. 1 is rather restricted to a narrow range. This is because the mapping of statistical quantities from real to redshift space is intrinsically nonlinear. Even at large scales, higher-order contributions to the mapping formula are not negligible. This is the main reason why there have been several improved models of RSD proposed so far on top of the perturbative treatment of nonlinear gravitational evolution by adding correction terms to the Kaiser formula in Eq. 1. Taking account of those effects is thus crucial and essential for an unbiased parameter estimation in the practical data analysis. On the other hand, the estimation of statistical errors is not usually much dependent on those elaborate factorized formulations, because the statistical error of each parameter mainly comes from the measurement uncertainties, including the cosmic variance and shot noise. Unless the significant contribution of higher-order corrections arises, the structure of parameter degeneracy would remain unchanged. Hence, in this paper, we do not consider higher-order corrections.

Nevertheless, the suppression of clustering amplitude due to the random motion is known as a non-perturbative effect, which significantly affects the power spectrum even at large scales, and should be accounted in the basic formulation of Eq. 1. Here, we assume that this FoG is given as a factorized form, and multiplied as (e.g., 22, 23, 31):

$$P(k) = D_{\text{FoG}}^p(k)P_{\text{lin}}(k).$$

The $D_{\text{FoG}}^p(k)$ is given by the Gaussian form as,

$$D_{\text{FoG}}^p(k) = \exp\left[-(k\mu\sigma_p)^2\right],$$

where $\sigma_p$ denotes the dispersion of the one-point PDF of the velocity in one-dimension. Note that at smaller scales, the virial motion of galaxies inside the cluster of galaxies also leads to a suppression of the power spectrum in redshift space. When $(k\mu\sigma_p)^2 \ll 1$, the leading order of Eq. 3 is dominant over all other higher orders, and the estimated errors are immune from the exact functional form of Eq. 3. The linear $\sigma_p$ is used for the fiducial value.

### B. Bispectrum

While the initial condition for perturbations is assumed to be Gaussian, gravitational evolution naturally induces the mode-mode coupling, giving rise to the non-vanishing bispectrum. Further, coupled with galaxy bias and RSD, the bispectrum in redshift space becomes rather complicated. The resultant leading-order expression for bispectra (e.g., [31]), valid at large scales, is given by,

$$\tilde{B}_{\text{pt}}^B(k_1, k_2, k_3) = 2 \left[ Z_2(k_1, k_2)Z_1(k_1)Z_1(k_2)P(k_1)P(k_2) \right] + \text{cyclic}$$

The kernel $Z_2$ is defined as,

$$Z_2(k_1, k_2) = \frac{b_2}{2} + bF_2(k_1, k_2) + f\mu_2^2G_2(k_1, k_2) + \frac{f\mu_1\mu_2}{k_1} \left[ \frac{\mu_1}{k_1}(b + f\mu_2^2) + \frac{\mu_2}{k_2}(b + f\mu_2^2) \right] + \text{cyclic},$$

where we define $\mu_i = (k_i \cdot \hat{z})/k_i$, $k_{ij} = k_i + k_j$, $\mu_{ij} = (k_{ij} \cdot \hat{z})/k_{ij}$, with $\hat{z}$ being the line-of-sight unit vector. Here, we incorporate the uncertainty of the nonlinear galaxy bias characterized by $b_2$ into the kernel $Z_2$, adopting the local bias prescription (e.g., [31]), i.e., $\delta_m = b\delta_m + b_2\delta_m + \cdots$. In the above, the functions $F_2$ and $G_2$ are the standard PT kernel in real space, given by,

$$F_2(k_1, k_2) = \frac{5}{7} + \frac{\eta_{ij}}{2}\left(\frac{k_i}{k_{ij}} + \frac{k_j}{k_{ij}}\right) + \frac{2}{7}\eta_{ij}$$

$$G_2(k_1, k_2) = \frac{3}{7} + \frac{\eta_{ij}}{2}\left(\frac{k_i}{k_{ij}} + \frac{k_j}{k_{ij}}\right) + \frac{4}{7}\eta_{ij}^2,$$

with $\eta_{ij} = (\vec{k}_i \cdot \vec{k}_j)/(k_i k_j)$. Note that the configuration of bispectra satisfies the triangular condition, which is expressed by the directional vector constraint,

$$\vec{k}_1 + \vec{k}_2 + \vec{k}_3 = 0.$$

In contrast to the redshift-space power spectrum, the influence of nonlinear RSD on Eq. 3 is not yet fully understood and studied in detail. Although it deserves further investigation, we can make the best guess on the possible damping effect due to the random motion of galaxy. The FoG effect in the bispectrum is assumed to be Gaussian as [32],

$$D_{\text{FoG}}^B(k_1, k_2, k_3) = \exp\left[-(k_1^2\mu_1^2 + k_2^2\mu_2^2 + k_3^2\mu_3^2)\sigma_p^2\right].$$

Then the observed bispectra are given by,

$$\tilde{B}(k_1, k_2, k_3) = D_{\text{FoG}}^B(k_1, k_2, k_3)\tilde{B}_{\text{pt}}^B(k_1, k_2, k_3).$$

Again, when $(k\mu\sigma_p)^2 \ll 1$, the detailed functional form of $D_{\text{FoG}}^B$ is not important for our estimation.

### C. Alcock–Paczynski test

In addition to the anisotropies induced by the RSD, the observed galaxy clustering also exhibits anisotropies through the Alcock–Paczynski (A-P) effect. This can
happen if the background expansion of the real universe differs from the fiducial cosmology used to convert the redshift and angular position of each galaxy to the co-moving radial and transverse distances. While this effect leads to the modulation in the shape and amplitude of power spectra and bispectra, if the shape of these quantities is a priori known, it offers a unique opportunity to measure the angular diameter distance $D_A(z)$ and Hubble parameter $H(z)$ of distant galaxies at redshift $z$ through the measurement of characteristic shape in both radial and transverse directions. Further provided the information on the evolution of density and velocity fields, the two types of apparent anisotropies (i.e., RSD and A-P effects) become distinguishable, and the geometric distances $D_A$ and $H$ are separately and accurately determined. This is indeed possible if we know at least the broadband shape of spectra. In other words, given a accurate theoretical template which describes the broadband shape of the power spectrum and bispectrum, the simultaneous constraints on the geometric distances and growth of structure are made possible. We dub this method as a broadband A-P test \[34\].

The anisotropies in the power spectrum caused by the A-P effect are modeled in a similar way, and the resultant shape of bispectrum depends on five parameters, i.e., $(k_1, k_2, k_3, \mu_1, \mu_2)$. The observed bispectra are thus related to the true one given in Eq. \[11\] through,

$$
\tilde{B}^{\text{obs}}(k_1, k_2, k_3, \mu_1, \mu_2) = \left( \frac{H^{\text{true}}}{H^{\text{fid}}} \right)^2 \left( \frac{D_A^{\text{fid}}}{D_A^{\text{true}}} \right)^2 \tilde{B}(q_i, \nu_i),
$$

where $(k, \mu)$ denotes the fiducial coordinates for the underlying cosmological model, and $(q, \nu)$ represents the coordinates in the true cosmology.

The A-P effect for bispectra is also modeled in a similar way, and the A-P effect for power spectra by $P$, the observed power spectrum becomes

$$
\tilde{P}^{\text{obs}}(k, \mu) = \left( \frac{H^{\text{true}}}{H^{\text{fid}}} \right)^2 \left( \frac{D_A^{\text{fid}}}{D_A^{\text{true}}} \right)^2 \tilde{P}(q, \nu),
$$

where $\langle q, \nu \rangle$ represents the coordinates in the true cosmology.

The relations between two coordinates are give by,

$$
q_i = \alpha(\mu_i)k_i,
$$

and

$$
\nu_i = \frac{\mu_i}{\alpha(\mu_i)} \frac{H^{\text{true}}}{H^{\text{fid}}},
$$

where $\alpha(\mu_i)$ is defined by,

$$
\alpha(\mu_i) \equiv \left\{ \left( \frac{D_A^{\text{fid}}}{D_A^{\text{true}}} \right)^2 + \left[ \left( \frac{H^{\text{true}}}{H^{\text{fid}}} \right)^2 - \left( \frac{D_A^{\text{fid}}}{D_A^{\text{true}}} \right)^2 \right] \mu_i^2 \right\}^{1/2}.
$$

The cosine of angle between two vectors, $\nu_{ij} = (\tilde{q}_i \cdot \tilde{q}_j)/(\tilde{q}_i \cdot \tilde{q}_j)$, is given by,

$$
\nu_{ij} = \left( \frac{D_A^{\text{fid}}}{D_A^{\text{true}}} \right)^2 \frac{\eta_{ij}}{\alpha(\mu_i)\alpha(\mu_j)} + \left( \frac{H^{\text{true}}}{H^{\text{fid}}} \right)^2 - \left( \frac{D_A^{\text{fid}}}{D_A^{\text{true}}} \right)^2 \} \frac{\mu_i\mu_j}{\alpha(\mu_i)\alpha(\mu_j)}. \quad (16)
$$

Here, we define $\eta_{ij} = (\tilde{k}_i \cdot \tilde{k}_j)/(k_i k_j)$.

### D. Covariance matrix and Fisher matrix analysis

In this paper, to elucidate the potential power of the bispectrum to constrain the cosmology, we shall specifically consider the Dark Energy Spectroscopic Instrument (DESI) as a representative future galaxy survey, and proceed to the Fisher matrix analysis. Primary science goal of the DESI experiment is to clarify the nature of dark energy and/or gravity through the A-P and RSD effects, and starting in 2018, it will obtain optical spectra for tens of millions of galaxies and quasars, constructing a 3-dimensional map spanning the nearby universe to 10 billion light years. DESI will be conducted on the Mayall 4-meter telescope at Kitt Peak National Observatory. It is supported by the Department of Energy Office of Science to perform this Stage IV dark energy measurement. The expected number density of the galaxies in terms of the co-moving volume is summarized in Table I.

| $z$  | $n_g \ [h^3 \text{Mpc}^{-3}]$ | $V_{\text{survey}} \ [h^{-3} \text{Gpc}^3]$ |
|------|-----------------------------|------------------------------------------|
| 0.6–0.8 | $1.2 \times 10^{-3}$ | 5.3 |
| 0.8–1.0 | $1.1 \times 10^{-3}$ | 7.0 |
| 1.0–1.2 | $5.4 \times 10^{-4}$ | 8.3 |
| 1.2–1.4 | $3.3 \times 10^{-4}$ | 9.4 |
| 1.4–1.6 | $1.5 \times 10^{-4}$ | 10.1 |
| 1.6–1.8 | $5.0 \times 10^{-5}$ | 10.6 |

**TABLE I:** Expected number density of galaxies $n_g$ and survey volume $V_{\text{survey}}$ at each redshift bin used in the Fisher matrix analysis. These specific values are taken from those assumed in the DESI experiment.

In order to compute the Fisher matrix, the error covariance of the power spectrum and bispectrum need to be evaluated. To simplify the analysis, we will ignore the off-diagonal components of the covariance matrices arising mainly from the nonlinear mode coupling. This would certainly lead to an optimistic estimation of the parameter constraints, however, it has been shown that in the case of power spectrum, the non-Gaussian error contribution to the off-diagonal components are small enough, and the diagonal components of the covariance matrix can be approximately described by the simple Gaussian contribution \[41\]. This would be true as long as we consider the quasi-linear scales at moderately high redshift (say, $z \gtrsim 1$ and $k \lesssim 0.15 \ h \text{Mpc}^{-1}$). The parameter estimation study with non-Gaussian covariance further revealed that the size of the constraints on each parameter
is not drastically changed if we consider the multiple parameter estimation (11, 42, see also [43]).

The Gaussian contribution to the covariance matrix for power spectra is given by,

$$C_{PP} = \frac{1}{N_P} \left[ Z_1^2(k, \mu) P(k) + \frac{1}{n_g} \right]^2,$$  \hspace{1cm} (17)

where $N_P$ is given by,

$$N_P = \frac{V_{\text{survey}}}{2(2\pi)^3} k^2 \Delta k \Delta \mu .$$  \hspace{1cm} (18)

Here the survey volume is derived by calculating the co-moving shell in each redshift bin, and multiply by fractional factor from DESI $f_{\text{sky}} = 14,000 \text{ deg}^2$. The Gaussian contribution to the covariance matrix for bispectra is expressed as,

$$C_{BB} = \delta_{\alpha\beta} s_B \frac{V_{\text{survey}}}{N_B} \left[ Z_1^2(k_1, \mu_1) P(k_1) + \frac{1}{n_g} \right] \left[ Z_1^2(k_2, \mu_2) P(k_2) + \frac{1}{n_g} \right] \left[ Z_1^2(k_3, \mu_3) P(k_3) + \frac{1}{n_g} \right] ,$$  \hspace{1cm} (19)

where $N_B$ is given by,

$$N_B = 2\pi k_1 k_2 k_3 (\Delta k)^2 (\Delta \mu)^2 \left[ \frac{V_{\text{survey}}}{(2\pi)^3} \right]^2 .$$  \hspace{1cm} (20)

The pre-factor $s_B$ is set to 6 for equilateral, 2 for isosceles, and 1 for general triangular configurations. Finally, the cross-covariance matrix between bispectrum and power spectrum is given by

$$C_{PB} = \frac{s_B}{N_P} \left( \delta_{k_1, k_2} P(k_1) + \frac{1}{n_g} \right) \left[ Z_1^2 P(k) + n_g^{-1} \right] \left[ Z_1^2 P(k_2) + n_g^{-1} \right] \left[ Z_1^2 P(k_3) + n_g^{-1} \right] \left[ Z_1(k_1, \mu_1) Z_1(k_2, \mu_2) \right] + \text{cyclic} \right),$$ \hspace{1cm} (21)

Notice that while the covariance matrices, $C_{PP}$ and $C_{BB}$, can be expressed as a diagonal form, the full matrix of $C$ combining both power spectrum and bispectrum is no longer diagonal even in the Gaussian case. This generally requires a complicated matrix algebra, however, the covariance matrix $C$ in our case can be expressed in a block-diagonal form as,

$$C = \begin{pmatrix} C_{PP} & C_{PB} \\ C_{BP} & C_{BB} \end{pmatrix}.$$  \hspace{1cm} (22)

Then the inverse matrix $C^{-1}$ is expressed as,

$$C^{-1} = \begin{pmatrix} M & -M C_{PB} C_{BB}^{-1} \\ -C_{BB}^{-1} C_{BP} M & C_{BB}^{-1} + C_{BB}^{-1} C_{BP} M C_{PB} C_{BB}^{-1} \end{pmatrix}$$

with the matrix $M$ given by $M \equiv (C_{PP} - C_{BB} C_{BP}^{-1} C_{BB})^{-1}$. Note that with the Woodbury formula $M = C_{PB}^{-1} - C_{PB}^{-1} C_{BP} (C_{BB}^{-1} + C_{BP}^{-1} C_{PB}^{-1})^{-1} C_{BP} C_{PB}^{-1}$, we easily verify that $C C^{-1} = C^{-1} C = I$.

With the full covariance matrix given above, the Fisher matrix combining the power spectrum and bispectrum becomes

$$F_{\alpha\beta} = \sum_{\vec{k}} \sum_{\vec{k}_1, \vec{k}_2, \vec{k}_3} \frac{\partial \tilde{S}_{\text{obs}}}{\partial x_{\alpha}} C^{-1} \frac{\partial \tilde{S}_{\text{obs}}}{\partial x_{\beta}} ,$$  \hspace{1cm} (23)

where $x_{\alpha}$ indicates the parameters for our interest, i.e., $DA$, $H^{-1}$, and so on. The quantity $\tilde{S}_{\text{obs}}$ is the signal vector expressed as

$$\tilde{S}_{\text{obs}} = \left( \tilde{P}_{\text{obs}}(\vec{k}) \tilde{B}_{\text{obs}}(\vec{k}_1, \vec{k}_2, \vec{k}_3) \right).$$  \hspace{1cm} (24)

Below, we will present the results in four different cases: 1) power spectrum only, 2) bispectrum only, 3) power spectrum and bispectrum, but cross covariance ignored [Eq. (25)], and 4) full information taking account of the non-vanishing cross covariance [Eq. (23)].

### III. RESULTS

In this section, we present the results of Fisher matrix forecast described in the previous section. In what follows, the cosmological parameters needed to compute the power spectrum and bispectrum are set to the Planck 2013 concordance model (43): $\Omega_m = 0.32$, $\Omega_b = 0.049$, $h = 0.67$, $A_S = 2.15 \times 10^{-9}$ and $n_S = 0.96$. In our Fisher matrix, the number of parameters to be determined by observations is basically 6, i.e., geometric distances $D_A$ and $H^{-1}$, growth of structure $f$, galaxy biasing $b$ and $b_2$, and FoG damping $\sigma_p$. While the fiducial values of the first three parameters are specified by the cosmological parameters of the underlying cosmological model, the last three parameters are the nuisance parameters, for which we assume that the observed galaxy distribution faithfully traces the mass distribution. That is, the galaxy bias $b$ and $b_2$ are respectively set to 1 and 0, and the fiducial value of $\sigma_p$ is just given by the linear theory prediction.

### A. Signal-to-noise ratio

Before discussing the constraints on each parameter, we first look at the signal-to-noise ratio $S/N$, and check
the potential power of the bispectrum relative to that of the power spectrum. We compute the \( S/N \) for both the power spectra and bispectra at each redshift bin. The signal-to-noise ratio for the power spectra and bispectra, \( (S/N)_p \) and \( (S/N)_b \), are respectively defined as,

\[
\left( \frac{S}{N} \right)_P = \sum_k \frac{\tilde{B}^2(k)}{C_{PP}}, \quad (26)
\]

\[
\left( \frac{S}{N} \right)_B = \sum_{k_1,k_2,k_3} \frac{\tilde{B}^2(k_1,k_2,k_3)}{C_{BB}}. \quad (27)
\]

Similarly, we define the signal-to-noise ratio for the combined case:

\[
\left( \frac{S}{N} \right)_{P+B} = \sum_k \sum_{\vec{k}_1,\vec{k}_2,\vec{k}_3} \tilde{S} \tilde{S}^* \frac{C^{-1}}{C_{BB}}. \quad (28)
\]

Here, the vector \( \tilde{S} \) is similarly defined as Eq. (24), but the quantities \( \tilde{P}_{\text{obs}} \) and \( \tilde{B}_{\text{obs}} \) are replaced with \( \tilde{P} \) and \( \tilde{B} \) [Eqs. (3) and (11)].

In the Fig. 1, we plot the three different \( (S/N) \) defined above, adopting the specific survey design of DESI. Note that in all cases, the cut–off wavenumber \( k \) is set to be \( k = 0.1 \, h \, \text{Mpc}^{-1} \). The dotted and dash curves represent the \( S/N \) for power spectrum and bispectrum, respectively. The signal–to–noise for bispectrum is basically smaller than that for power spectrum. Nevertheless, the combination of bispectrum with power spectrum helps to improve the signal–to–noise ratio, as shown in solid curve, and the improvement becomes significant as decreasing the redshift. This is because the number density of galaxies becomes larger at lower redshift in our setup (Table I). Then, the shot noise contribution can be suppressed at a relatively larger wavenumber. Given the fact that the number of available configurations or modes in bispectrum more rapidly increases with the wavenumber than that in power spectrum, \( (S/N)_B \) eventually exceeds \( (S/N)_P \) at the first redshift bin, although the cosmic variance error now comes to play an important role and the total signal-to-noise is slightly reduced compared to the one at the second redshift bin.

**B. Constraints on the geometric distances**

As we mentioned in Sec. 1, precision measurement of BAO is the key to determine the geometric distances, \( D_A(z) \) and \( H^{-1}(z) \), through the A-P effect. Although the acoustic structure imprinted on the power spectrum and bispectrum actually depends on cosmology, the counterpart of the acoustic oscillations is precisely observed in the CMB anisotropies, and with the cosmological results by WMAP and Planck as prior information, BAO can be used as standard ruler. At \( k \lesssim 0.1 \, h \, \text{Mpc}^{-1} \), the galaxy power spectrum and bispectrum are supposed to be described by the leading-order perturbation, where the acoustic signature is clearly visible. In the presence of the galaxy bias, the only uncertainty is the clustering amplitude, however, this does not seriously affect the measurement of the characteristic scales of BAO.

In Fig. 2, the forecast result for the statistical errors of the angular diameter distance \( D_A \) is shown. The fractional errors are presented in the lower panel. With the DASI-like survey, constraints on \( D_A \) from the power spectrum (dotted) and bispectrum (dashed) become comparable at lower redshift, \( z \lesssim 1.2 \), and precision is typically 1–2% level, although the constraining power of the bispectra becomes rapidly worsen as increasing the redshifts. Note that if all the other parameters such as growth rate \( f \) and galaxy bias are known a priori, \( D_A \) can be measured with sub–percentage accuracy. However, the growth rate and the linear bias are mostly degenerate with \( D_A \), particularly in the limit of \( \mu \to 0 \). Combining both the power spectrum and bispectrum, depicted as dash-dotted line, the constraint on \( D_A \) will be improved by a factor of 1.5, thus mostly achieving a sub-percent precision.

Note that a comparable result of the constrained values from the power spectra and bispectra is understood from the signal–to–noise in Fig. 1. The signal–to–noise for bispectrum is higher than that of the power spectrum at low redshift bins, at which the number of observed galaxy is smaller than that of the power spectrum. Nevertheless, the combination of bispectrum with power spectrum helps to improve the signal–to–noise ratio, as shown in solid curve, and the improvement becomes significant as decreasing the redshift. This is because the number density of galaxies becomes larger at lower redshift in our setup (Table I). Then, the shot noise contribution can be suppressed at a relatively larger wavenumber. Given the fact that the number of available configurations or modes in bispectrum more rapidly increases with the wavenumber than that in power spectrum, \( (S/N)_B \) eventually exceeds \( (S/N)_P \) at the first redshift bin, although the cosmic variance error now comes to play an important role and the total signal-to-noise is slightly reduced compared to the one at the second redshift bin.

**FIG. 1: Signal-to-noise of power spectrum (dotted) and bispectrum (dashed) as function of redshift. Assuming a DESI-like experiment, the signal-to-noise ratios defined at Eqs. (26) and (27) are estimated at each redshift bin. The combined result of the power spectrum and bispectrum, taking account of the cross covariance, is plotted as solid line [see Eq. (28) for definition].**
FIG. 2: Upper: The expected $1\sigma$ error of the angular diameter distance $D_A(z)$ for DESI-like experiment. The size of the errorbars corresponds to the marginalized $1\sigma$ error estimated from the Fisher matrix, combining both the power spectrum and bispectrum. Lower: The fractional errors of $D_A$. The dotted curve represent the constraints using power spectrum only, while the dashed curve shows the results using bispectrum only. The solid and the dot–dashed lines represent the results combining both the power spectrum and bispectrum, taking account of the full covariance and only the diagonal components of the covariance, respectively.

from power spectra in the first two redshift bins, as shown in Fig. 2. Even if $n_{\text{gal}}$ decreases but still exceeds $10^{-4} \ (h^3\text{Mpc}^{-3})$, the constraints from bispectra are comparable to those from power spectra. Thus, combining both power spectra and bispectra provides an opportunity to improve the constraints on $D_A$.

On the other hand, the determination of radial distance $H^{-1}$ is more difficult than that of $D_A$. The redshift dependence of the error on $H^{-1}$ is presented in Fig. 3. The dotted and dashed curves represent the constraints using the power spectra and bispectra, respectively. The information on $H^{-1}$ is most imprinted at the limit of $\mu \rightarrow 1$, at which the observed spectra is influenced by RSD, mainly due to the non–linear smearing effect. Because of this, the resultant statistical precision is poorer than that of $D_A$ by a factor 2. Comparing between solid and the dotted–dash curves, the off–diagonal elements of the covariance matrix do not much reduce the constraining power.

FIG. 3: Upper: Expected $1\sigma$ errors on the comoving radial distance, given by the inverse Hubble parameter $H^{-1}(z)$, assuming DESI-like survey. The results combining both the power spectrum and bispectrum are shown. Lower: The fractional errors of $H^{-1}$ using DESI are presented. Meaning of the line types are the same as in Fig. 2.

FIG. 4: Two-dimensional contour of the expected $1\sigma$ constraint on the parameters $f$ and $\sigma_8$. The results at the redshift bin of $0.6 < z < 0.8$ is particularly shown. The dotted contour represents the case of power spectra, the dash contour represents the case of bi spectra, and the solid curve represents the case of the combination.
C. Constraints on the growth of structure

At the scales close to the linear regime, the improved theoretical model of RSD successfully can describe the observed spectra. Still, however, nonlinear cross talk of the small-scale physics with large-scale anisotropic clustering (i.e., FoG effect) is significant, and a proper treatment of this cross talk needs to be incorporated. Here, we adopt the simple Gaussian forms to phenomenologically describe the FoG effect [see Eqs. (4) and (10)]. This would certainly remedy the flaw in the perturbative modeling of RSD, but the strength of the damping characterized by $\sigma_p$ is now a free parameter, which needs to be determined by observations.

Fig. 4 shows the impact of this uncertainty in constraining the growth of structure. Here, the plotted result is the two-dimensional contour of the expected 1σ constraint, which is estimated at the specific redshift bin, $0.6 < z < 0.8$. The parameter $\sigma_p$ is significantly correlated with the linear growth rate $f$, and the analysis using the power spectrum alone, depicted as dotted contour, exhibits a strong parameter degeneracy. This is partly due to the small cutoff wavenumber, $k_{\text{max}} = 0.1 \, h \, \text{Mpc}^{-1}$, below which the damping term, expressed as function of $(k\mu)^2$, is monotonically varies along the direction $\mu$, and the behavior looks very similar when we vary $f$. The situation almost remains unchanged even if we use the bispectrum, and the strong degeneracy between $f$ and $\sigma_p$ is observed (dashed contour). Interestingly, however, the direction of parameter degeneracy differs from that of the power spectrum case. Accordingly, the combination of the power spectrum and bispectrum improves the constraint on $f$.

Figs. 5 and 6 respectively show the marginalized results of the fractional errors on $f$ and $\sigma_p$, plotted as a function of redshift. Combining power spectrum and bispectrum, the constraint on $f$ becomes tighter at all redshift bins. In particular, at lower redshift bins, statistical power of the bispectrum is enhanced, and the relative impact on the constraint on the parameter $\sigma_p$ becomes eventually stronger (see bottom panel of Fig. 6). As a result, compared to the power spectrum results, the combined result of the constraint on $f$ is improved by a factor of 2. Note that similar to the constraints on the geometric distance, a role of off-diagonal component of the error covariance is insignificant in the case of $f$ and $\sigma_p$, and it does not change the results so much.

Finally, to see the impact of the FoG effect on the measurement of growth rate, we plot in Fig. 7 the marginalized constraints on $f$ in the case when we know the FoG effect a priori. As it is expected, the parameter $f$ is better constrained, and the precision reaches at $\sim 2\%$ level. One notable and interesting point is that the power spectrum always gives a tighter constraint, and combination of power spectrum and bispectrum does not improve much the constraint. Thus, the benefit of using the bispectrum is substantially reduced.
D. Constraints on the galaxy bias parameters

Fig. 8 shows the forecast result of the statistical errors on galaxy bias parameters. The upper panel presents the constraint on the linear bias parameter $b$. The linear bias is tightly constrained by the power spectrum depicted as dotted line, and no benefit to use the bispectrum is found (dashed), although the combination of power spectra and bispectra still improves the constraint by a factor of 2 (solid). This is because of another bias parameter $b_2$, which coherently boosts the amplitude of bispectrum. Also, one important assumption here is that the cosmological parameters are known a priori from the CMB observations, including the normalization of linear power spectrum. In other words, if the specific cosmological models are not given, the linear bias information is not extracted from the power spectrum.

On the other hand, the bottom panel of Fig. 8 shows the constraint on the nonlinear bias parameter $b_2$. The power spectrum alone cannot constrain $b_2$, because the parameter $b_2$ does not appear in the expression of power spectrum, relevant at the large scales of our interest (see Sec. II A). Even using the bispectrum, $b_2$ is poorly constrained. This is due to the degeneracy between the bias parameters $b$ and $b_2$. In this respect, the combination of the power spectrum and bispectrum is quite essential to break the degeneracy. With a help of the power spectrum information, $b$ is measured precisely, and this will lead to a substantial improvement of the constraint on $b_2$, as shown in solid line.

IV. SUMMARY

The bispectrum has been recognized as a powerful tool to probe non–Gaussian initial conditions, and to enhance the constraints on BAO distance measures. In this paper, we highlighted the benefit to improve the simultaneous constraint on the growth of structure, and geometric distances through RSD and A-P effect. The power spectra in redshift space suffer from the nonlinear cross talk between small- and large-scale clustering, and the clustering amplitude is significantly suppressed at large scales. While the impact of this FoG effect is less significant at the scales close to the linear regime, it is difficult to break degeneracy between the distortions induced by coherent motions and systematics arising from the FoG effect. Although this would be certainly resolved with a better understanding of the nonlinear cross talk based on a more elaborate theoretical model, we here proposed an alternative way to improve the cosmological constraints by using both the power spectrum and bispectrum. Assuming the DESI-like experiment, Fisher matrix analysis suggests that the analysis using the power spectrum data alone shows a strong parameter degeneracy between the growth of structure ($f$) and $\sigma_8$ as a nuisance parameter characterizing the damping scale of the FoG effect. Then, the estimated errors on $f$ is about 5% at the best redshift bin. We found that this parameter degeneracy can be broken when combining both the power spectrum and bispectrum. As a result, the constraint will be improved by a factor of two, which satisfies the primary science goal to distinguish the possibilities to explain the cosmic acceleration, i.e., the dark energy and modification of gravity on cosmological scales.

Note finally that these results certainly depend on the model of the FoG effect. This is especially the case for the bispectrum. While we adopted a simple Gaussian ansatz to describe the FoG damping, a proper way to characterize the FoG effect in bispectrum is not fully understood. Different assumption or prescription of the FoG effect is possible, and may lead to a quantitatively different result. We leave this issue for the further work.
