Spiral Dynamics in Pattern-Forming Systems: Mean Flow Effects

Lev S. Tsimring

Institute for Nonlinear Science, University of California at San Diego, La Jolla, CA 92093-0402

Abstract

Mean flow effects are discussed for two different pattern-forming systems: Rayleigh-Bénard convection and Faraday instability in viscous fluid. In both systems spirals are observed in certain parameter regions. In the Rayleigh-Bénard convection, the spiral core instability and subsequent generation of up- and downflow hexagons are shown to occur due to the mean flow generated by the curved rolls near the core. In the Faraday instability, the mean flow which is generated by rapidly decaying surface waves near the wall, causes wavenumber frustration which leads to a rigid-body spiral rotation. In both cases we use phenomenological Swift-Hohenberg-type equations for the order parameter coupled to a large-scale mean flow. Numerical simulations are compared to recently reported experimental results.

1 Introduction

Nonlinear evolution of cellular patterns in extended systems near the threshold of a primary instability are usually studied using amplitude equations (e.g., Newell-Whitehead-Segel equation for roll patterns in isotropic systems[1]). These amplitude equations can be derived from the first principles by perturbative expansion using the supercriticality $\epsilon$ as a small parameter. However, the expansion is based on a pre-chosen orientation of the cellular pattern and thus do not preserve the full spatial symmetry of the physical system. Therefore this description fails for more complicated patterns such as coexisting domains with varying orientation of rolls, targets, spirals, etc. To overcome this
difficulty, phenomenological models similar to the so-called Swift-Hohenberg equation (SHE),
\[
\frac{\partial \psi}{\partial t} = \epsilon \psi - (1 + \nabla^2)^2 \psi - \psi^3
\]  
(1)

are often employed (see [2] and references therein). This model correctly describes the linear properties of the system close to the threshold and yet preserves the rotational symmetry of the system. The disadvantage of this approach is that the nonlinear term in this equation is usually added \textit{ad hoc} in order to provide a saturation of the primary instability and cannot be systematically derived from underlying first principles. Thus, while some of the features (including some secondary instabilities, domain coarsening, etc.) of the pattern formation can be modeled based on this equation, some other essential features of the dynamics may be missing. In many examples these features are related to the coupling between the cellular mode and so-called zero mode slowly varying both in space and time. It can be a concentration field in binary-fluid convection[3], population inversion in extended lasers[4], density field in granular media[5], mean flow in Rayleigh-Bénard convection[6–8]. This problem can be rectified by expanding the basic model (1) so that it includes the interaction with the zero mode. It allows to reproduce many subtle features of the dynamics of cellular patterns within a simple phenomenological description.

In this paper we illustrate these general ideas by two examples of spiral dynamics in Rayleigh-Bénard convection and oscillating fluid layer. In both cases the spiral rotation is intimately related to the interaction with mean flow, self-generated by the cellular patterns in case of convection, and wall-generated in case of Faraday system. We show that recently observed spiral core instability[9,10] and spiral-hexagon transition[10] in Rayleigh-Bénard convection in Boussinesq fluid can be understood within the model for the order parameter coupled with the mean flow[11]. We also demonstrate that spiral rotation in Faraday experiment can be explained by the wavenumber frustration which is caused by the near-wall radial mean flow generated by decaying capillary waves[12].

2 Spirals in Rayleigh-Bénard convection

Recently discovered spiral-defect chaos (SDC) in large aspect ratio Rayleigh-Bénard convection system at small Prandtl number[13] was successfully reproduced both within Navier-Stokes equations[14] and also using SHE coupled to the equation for the mean flow generated by the curved rolls[15],
Here $\psi$ is the order parameter, $u$ the horizontal velocity field of the large-scale flow, and $\Omega$ the vertical component of the vorticity. The control parameter $\epsilon$ represents the reduced Rayleigh number, while $\sigma$ characterizes the Prandtl number of the fluid. The parameter $g$ allows to more accurately reproduce the stability properties of convection patterns[8], and $g_m$ characterizes the coupling strength between the order parameter $\psi$ and the vorticity $\Omega$. The phenomenological parameter $c$ is introduced to describe the local dissipation of the vorticity (e.g. due to friction at the bottom of the convection cell)[8,2]. Thus, Eq. (2) describes the dynamics of the order parameter $\psi$, while Eq. (3), using the definition of the vorticity (4), represents the coupling of the large-scale flow field $u$ and the order parameter. For $g = 1$ and $g_m = 0$ Eqs. (2)-(4) reduce to the Swift-Hohenberg equation (1). We solved Eqs. (2)-(4) numerically in a domain of $256 \times 256$ collocation points using a pseudo-spectral method based on the Fast Fourier Transform. The physical domain size was typically restricted to $150 \times 150$. Circular boundary conditions were enforced by ramping $\epsilon$ towards negative values at distances from the center $r > R_{\text{max}} = 55$.

Essential features of SDC include spontaneous spiral creation, quasi-stationary spiral rotation, spiral core instability, and eventual spiral destruction by other spirals. Cross and Tu[16] showed that persistent spiral rotation is caused by the wavenumber frustration between the values selected by the spiral core and by the environment (most typically, roll dislocations). It is noteworthy that large vorticity generated in the spiral core plays only the secondary role in this mechanism since the asymptotic wavenumber selected by the core does not depend on the Prandtl number and coupling to the mean flow (parameter $g_m$ in Eq.(3)). However, vorticity plays a major role in wavenumber selection by the roll dislocation. It is easy to see that the dislocation in the roll pattern generates a vortex pair which drives the dislocation towards the half-plane with greater wavenumber (see Fig.1 where the order parameter for individual spiral terminated by a dislocation is shown together with corresponding mean flow vorticity). At small $g_m \epsilon$ the dislocation climbing speed due to vorticity is $v \propto g_m \epsilon$. The dislocation is stationary when this mean-flow drift is balanced by the ordinary climbing velocity $v_c \propto (1 - \alpha d)^{3/2}[17]$, therefore the selected wavenumber $q_{d0} \propto 1 - \alpha (g_m \epsilon)^{2/3}$ ($\alpha$ is a constant depending on other parameters $g$, $\sigma$, $c$). In a stationary rotating spiral, wavenumber $q_d$ near the dislocation is larger than $q_{d0}$ so the dislocation moves around the core of the spiral with an angular velocity coinciding with the frequency of the core rotation. It is easy to see from the phase diffusion equation (see [16]) that the frequency of the spiral rotation is inversely proportional to the distance from the core to the dislocation. Detailed measurements of individual spiral rotation rate confirms
At large supercriticality, a novel instability of the spiral core was recently observed[9,10]. The core exhibits high-frequency oscillations (with a period of several vertical diffusion times as compared with a period of overall spiral rotation of a few hundred vertical diffusion times). Using phase approximation (see [2,16]) it is easy to see that this instability is caused by the large vorticity generated near the core of the spiral. Indeed, in the phase approximation, outside the core of the spiral the phase is described by

$$\theta_t + U \cdot \nabla \theta = \tau(q)^{-1} \nabla \cdot [qB(q)]$$

(5)

where \( \tau(q) \), \( B(q) \) are known functions of the wavenumber \( q = \nabla \theta \) (\( B(1) = 0 \), \( B(q_d) < 0 \) for SHE),see [2]. For stationary rotating \( n \)-armed spiral, \( \theta = \int q(r)dr + n\phi - \omega t \), and therefore local wavenumber \( q(r) \) obeys the following ODE,

$$\omega = -\frac{\Gamma}{r^2} - \tau(q)^{-1} \frac{d}{dr}[qB(q)],$$

(6)

where \( \Gamma \) is a total circulation of the mean flow around the spiral core. It is easy to see that for \( 1 - q_d \ll 1 \) the wavenumber \( q(r) \approx 1 - A_1 r - A_2 n\Gamma/r^2 \) where \( A_{1,2} \) are constants depending on \( \tau \) and \( B \). The wavenumber slowly rises towards the core and then rapidly decreases in its near vicinity. Of course, this expression is only valid outside the core of the dislocation (\( r > 1 \)), however it illustrates the tendency for the core vortex to locally unwind the spiral. If \( \Gamma \) gets large, the wavenumber near the core goes outside the stability balloon and the spiral core becomes unstable. Visually it appears as that the core rotates against the overall spiral rotation (see a series of snapshots in Fig.2 and computer movie at [http://inls.ucsd.edu/~lev/conv/]). This behavior is qualitatively similar to observed in recent experiment by Plapp and Bodenschatz[9]. The threshold of this core instability depends on both \( \epsilon \) and \( g_m \) as well as the topological charge \( n \), see Fig.3.

For yet larger values of supercriticality, a transition to hexagons in the core of the spiral occurs, see Fig.4. Both up- and down-flow hexagons are generated simultaneously near the core of the spiral. The existence of stable hexagons in systems without quadratic nonlinearity such as Swift-Hohenberg which preserves the symmetry \( \psi \rightarrow -\psi \), was attributed to the spontaneous excitation of the zero mode by Dewell et al [19]. It should be noted that within the framework of pure variational SHE (1) the hexagonal state can only be metastable, so a domain of roll will always expand towards a domain of hexagons. In case of SHE coupled with mean flow, the zero mode is generated and stabilized near the core by the mean flow which unwinds the spiral and drives the wavenumber towards zero. This zero mode gives rise to a proliferation of hexagons near
the core of the spiral. This transition was observed experimentally in [10,11] (see Fig.5).

3 Spirals in a Faraday system

Parametric instability of a flat fluid surface subject to vertical oscillations remains a popular experimental tool for various pattern formation phenomena. Squares, rolls, hexagons and higher-order quasi-patterns have been observed in different regions of parameters (viscosity, driving frequency, and depth of the fluid layer). Phase diagram of different patterns has been recently computed by Chen and Viñals based on the Navier-Stokes equations[20]. In the region of large viscosity and large $h/\lambda$, straight rolls are a stable pattern. However, as in case of Rayleigh-Bénard convection, stable rotating spirals have been recently observed in the same parameter region[21,12]. In this section we discuss the origin of the spiral rotation within the order-parameter model for the parametric instability,

$$\frac{\partial \psi}{\partial t} = \gamma \psi^* - \nu \psi - (1 + i\alpha)|\psi|^2 \psi + i\kappa(\nabla^2 + 1)\psi - (u \cdot \nabla)\psi$$  

(7)

Here $\psi$ is a complex amplitude of surface oscillations at the parametric frequency $\omega_0$ (which is a half of the driving frequency), $\gamma$ is a forcing magnitude, $\kappa$ is the dispersion parameter, and $u$ is the velocity of the mean flow. Linear terms in this equation can be derived from the dispersion relation for capillary waves under parametric excitation, expanded near $\omega = \omega_0$, $q = 1$. The nonlinear term cannot be derived rigorously, as in Eq.(2) for Rayleigh-Bénard convection, and has been added ad hoc to account for the stabilization of the parametric instability. Imaginary part of the nonlinear coefficient $\alpha$ describes nonlinear frequency shift (see also [22]).

The last term in the r.h.s. of Eq.(7) describes order parameter advection by the mean flow. Such mean flow was observed in experiments [12] near the walls of the cavity. This flow is caused by the momentum transfer from dissipating capillary waves at the driving frequency which are generated by oscillating side walls. This flow is directed off the walls near the surface and due to incompressibility returns back to the walls near the bottom Velocity $u$ in (7) should be understood as an the average velocity over layer thickness weighted with the vertical structure of waves. Since surface waves decay towards the bottom, near-surface flow affects them stronger than near-bottom return flow and the net $u$ is oriented towards the center of the cavity.

Equation (7) with periodic boundary conditions was studied numerically using pseudo-spectral split-step method with $256 \times 256$ collocation points, domain
size \( d = 200 \) and integration time step 0.05. To simulate waves in circular cavity, we ramped linear dissipation outside the circle of radius \( r_0 = 86 \), i.e. \( \nu = \nu_0, r < r_0 \) and \( \nu = \nu_0(1 + k (r - r_0)), r > r_0 \), where \( k \) varied between 0.5 and 1.0. We assumed that the flow had radial direction and was azimuthally symmetric, \( \mathbf{u} = u(r) \hat{r} \). We used the following profile for flow velocity \( u(r) \):

\[
u = \nu_0 \exp[\xi (r - r_0)]
\]

For \( \gamma > \nu \) trivial state \( \psi = 0 \) is unstable with respect to perturbations with wavenumbers near 1. Numerical simulations show that at the nonlinear stage, these perturbations give rise to various cellular patterns, including plane waves, targets and spirals. Without mean flow term \( (u_0 = 0) \), these patterns remain stationary even when nonlinear coefficient in (7) is complex. Nonlinear frequency shift \( \alpha \) only leads to deviation of the selected wavenumber from \( q = 1 \). [In systems with ordinary (non-parametric) pattern-forming instabilities non-potential effects usually lead to wave propagation.] However, when near-wall flow \( (8) \) is introduced in (7), standing waves comprising targets and spirals begin to drift slowly toward the center. Figure 6 shows rolls velocity as a function of \( u_0 \) and \( \xi \). Note that \( \xi \gg r_0^{-1} \) so the flow is absent in the bulk, still rolls are moving throughout the integration domain. The phase velocity of rolls grows linearly with \( u_0 \) as it should be expected.

This phenomenology can be understood in terms of the phase diffusion equation similar to Eq.(5) for Rayleigh-Bénard system. The important difference is that here we have standing waves, and therefore two phases \( \theta_+ \) and \( \theta_- \) should be introduced. However, for large parametric forcing, the sum of phases \( \theta_+ + \theta_- \) is slaved to the phase difference \( \Theta = \theta_+ - \theta_- \). The equation for the latter reads

\[
\partial_t \Theta + U \cdot \nabla \Theta = \tau^{-1}(q) \nabla \cdot [qB(q)],
\]

where \( q = \frac{1}{2} \nabla \Theta \) and \( \tau(q), B(q) \) are functions of the wavenumber \( q \). For the spiral, \( \theta_{\pm} = \pm (\int qdr + m \phi) - \omega_{\pm} t \). Multiplying (9) by \( \tau(q) \) and integrating from \( r = 0 \) to \( R_{\text{max}} \) we obtain

\[
\omega_s \int \tau(q) dr = - \int U(r) q \tau(q) dr + qB(q)|_{r = R_{\text{max}}},
\]

where \( \omega_s = \omega_- - \omega_+ \) is a frequency of spiral rotation. For \( q \approx 1 \) the last term in (10) is small and the frequency of spiral rotation can be estimated as \( \omega_s \approx \int U(r) dr \approx u_0 \xi^{-1} \). This relation is in an agreement with numerical simulations (see Figure 6).

The mechanism of spiral rotation which we described is based on the assumption that the radial flow is produced by the rapidly decaying waves near the
wall generated by the oscillating meniscus. If this hypothesis is correct, the phase velocity of waves should increase linearly with the magnitude of driving. It also should depend sensitively on the wall profile. Indeed, experiment[12] confirmed this prediction (see Figure 7).

4 Conclusions

In this paper we briefly considered two different pattern-forming systems within the framework of order-parameter models coupled with mean flow. It turned out that both for Rayleigh-Bénard convection and Faraday system the mean flow plays a crucial role for spiral dynamics. In the former, vortex pairs generated by roll dislocations, move the selected wavenumber away from the value selected by the spiral core and lead to wavenumber frustration. The frustration in turn leads to the persistent spiral rotation. The strong vortex which is generated in the core of the spiral plays a minor role in the overall spiral rotation, however it leads to the local spiral unwinding and eventually to the spiral core instability. If the wavenumber near the core reaches zero due to local spiral unwinding, zero mode is generated and leads to proliferation of up- and down-flow hexagons.

In the Faraday system, stable rotating spirals have been recently observed. We showed that rotation of these spirals is caused by the near-wall radial flow which leads to the wavenumber frustration in the bulk. This near-wall flow is generated by rapidly decaying meniscus waves at the driving frequency.

The results presented in this paper have been obtained in collaboration with I.Aranson, M.Assenheimer, and V.Steinberg (Rayleigh-Bénard convection) and S.V.Kiyashko, L.N.Korzinov, and M.I.Rabinovich (Faraday system).
